Abstract

Characterization of Motor Oils and Other Lubricants by High Performance Liquid Chromatography, Three-Dimensional Excitation Emission Matrices and Two-Dimensional Low Temperature Fluorescence Spectroscopy

By

Kelly A. Walsh

Advisor: Dr. Thomas A. Kubic

Criminals often use automobiles during the commission of crimes. Criminalists routinely analyze automotive transfer evidence, including paint, rubber and glass in order to establish an association between a suspect car and a person or object that may have come in contact with that car. Currently, there is no routine forensic method to analyze transferred automotive undercarriage residue. This feasibility study will use fluorescence spectroscopy, both room-temperature and low-temperature (77K), and HPLC, to analyze this material and will investigate the use of compiled spectral libraries to assist in determining the evidentiary value of this process for this sample set.

Automobile undercarriage residues are a complex mixture of compounds from many sources including automotive fluids, asphalt residues, exhaust particulates and tire particulates. Each of these sources may contain compounds that fluoresce when

excited with light in the ultraviolet or visible region of the electromagnetic spectrum. Given the many sources of fluorescing compounds and the effect of environmental conditions on these compounds, it is hypothesized that the two-dimensional and three-dimensional fluorescence spectrum of automobile undercarriage residues along with HPLC analysis can be used to differentiate among automobiles.

Five undercarriage locations were swabbed from ten motor vehicles. Extraction via sonication in different solvents separated each residue into fractions. These fractions were analyzed by fluorescence spectroscopy and HPLC with UV detection. The types of fluorescence spectroscopy used were emission scans, synchronous scans, excitation-emission matrices, and low-temperature fluorescence spectroscopy. Previous studies with fluorescence characterization of lubricants relied on visual examination of the spectral data to determine differences or similarities (Purcell 2002). This study will use visual examination, peak number and position, chromatographic data and spectral libraries to show similarities and differences among the samples.

The research contributes to the body of knowledge about analytical methods that may characterize a long-observed transferable material, automotive undercarriage residue, to create associations between automobiles and persons or objects. These associations can be used to help the trier-of-fact decide upon the likelihood that an automobile came into contact with a person or object. Additionally, this research makes contributions to the field of environmental science which seeks to characterize petroleum-derived organic contaminants.

Acknowledgements

I would like to gratefully acknowledge the many people whose support was critical to my work. First and foremost, I owe a debt of gratitude to my mentor, Dr. Thomas A. Kubic, for his support, guidance and for an education that is singular and invaluable. Thank you for opening your life, lab and mind to me these past years. While I may have been of some assistance to you on various projects, it was always I who was the true beneficiary of our collaborations. This work would not have been possible without your continued guidance, advice and support. Many thanks to my additional committee members, Dr. John A. Reffner, Dr. Nicolas D. K. Petraco and Mr. Nicolas Petraco, Sr. Thank you for your sharing your wisdom and continued review and support of this work.

Additional thanks are owed to Drs. Selman Berger and Lawrence Kobilinsky, both chairmen of the Science Department at John Jay College during my time there. I am grateful for the supportive setting that the science department provided me as a student, researcher and instructor. I am additionally grateful for the support I received through the CUNY Graduate Center Criminal Justice PhD program as a graduate adjunct fellow and for the continued support of the CJ forensic science specialization during the chairmanships of Dr. Todd Clear, Dr. Karen Terry and Dr. Joshua Freilich.

Thank you to my parents for their unwavering encouragement. And finally, thank you to my husband, Dan, to whom this work is dedicated.

Introduction

The criminalist's analysis of transfer evidence can be a powerful tool to create associations. Incidents involving automobiles often yield several different types of transfer evidence. Transferred paint is primarily analyzed by light microscopy, infrared microspectrophotometry, pyrolysis gas chromatography-mass spectroscopy and scanning electron microscopy with energy dispersive X-ray spectrometry (Caddy 2001). The density, refractive index and elemental composition of transferred glass can be established. Transferred rubber is identified by attenuated total reflectance microspectrophotometry and pyrolysis gas chromatography. The results of these multi-instrumental analyses are compared to find a likelihood of association between an automobile and a person or object. Historically, this likelihood has been unquantifiable but forensic science researchers and practitioners are beginning to adopt a Bayesian approach to generating likelihood ratios (Taroni *et al*, 2010).

Missing from the list of regularly analyzed transfer evidence is automotive undercarriage residue. This material, mainly consisting of petroleum-derived products, is a complex, dynamic and easily transferable material. This study investigated the usefulness of liquid chromatography to adjust the concentration of fluorescing compounds, fluorescence spectroscopy to characterize automotive undercarriage residue and visual examination coupled with spectral library searching techniques to gauge the discriminatory power of the latter technique.

Contribution to the Field of Forensic Science and Criminal Justice

The contribution of this research to forensic science is the ability to use a long-observed transferable material, automotive undercarriage residue, to create associations between automobiles and persons or objects. These associations can be used to help the trier of fact determine the likelihood that a specific automobile came into contact with a person or object. This project illustrates the discriminatory power of transferred petroleum materials and the usefulness of fluorescence spectroscopy and high performance liquid chromatography with UV detection. This type of evidence is found in "hit and run" type vehicular crimes and in environmental crimes.

1. Vehicular Crimes

Incidents where a vehicle comes in contact with a person or object result in a several different types of transfer evidence. Glass, paint, and rubber transferred from a vehicle to person or object, and fibers and biological evidence transferred from person to vehicle are routinely analyzed to determine if contact took place. At present, the transfer of petroleum products from the vehicle to a person or object are not routinely analyzed. I suggest that automotive undercarriage residue analysis could be valuable in creating an association between a suspect car and person or object that came in contact with the underside of that vehicle. This association becomes valuable in the case of a hit-and-run incident where investigators may need to connect a suspect vehicle, not found at the scene but located at a later time, to a victim. If the victim made contact with the underside of the offending vehicle it is very likely that there was a transfer of automotive

undercarriage residue. Characterizing the fluorescing components of this residue by conducting a spectral comparison of the transferred and native materials could prove especially valuable in the efforts to associate a vehicle to a victim. This is especially true when there are no classic types of transfer evidence (e.g paint, glass) recovered or it is of little evidentiary value. In cases where the identity of the vehicle is known but the details of the collision are contested, automotive undercarriage reside may be helpful for reconstruction purposes (Purcell, 2002).

2. Environmental crimes

Oil spills on both ground and water are a much too frequent occurrence. These events have environmental, legal and financial consequences to the municipalities that detect and oversee the clean-up of the spilled petroleum products. For the fiscal year 2007 there were 527 oil spill incidents, both water and ground, in New York City (NYC DEP, 2007). Clean-up costs can vary wildly depending on such factors as type and amount of oil spilled, rate of spillage, spill location, weather, season and competence of clean-up personnel. It is not always clear, especially in heavily industrialized areas, where the spill originated and therefore what organization or company is the responsible party. Careful chemical analyses of the spilled material using chromatographic and spectroscopic methods have been successful in establishing the source of spilled petroleum materials (Zieba, 1985). This current research, despite its focus on automotive sources of transferred petroleum products, builds on the body of work regarding environmental crimes. Similar laboratory techniques can be used for environmental soil

or water samples. If this method proves to be highly discriminatory it would be extremely helpful in cases where there are hundreds of potential polluters. If culpability can be established in a greater percentage of oil spill events, then more of the clean-up costs can be shifted away from the taxpayer and onto the responsible party.

Instrumental Theory

1. Fluorescence and Phosphorescence

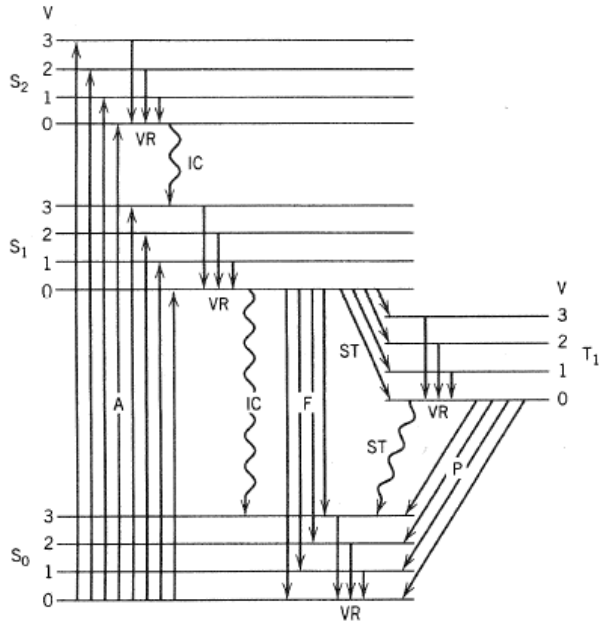
All electrons in an atom are represented by four quantum numbers; n, l, m_l, m_s. The principle quantum number, n, represents the energy of the orbital. The azimuthal quantum number, l, determines the shape of the orbital and the angular momentum of the electron. The magnetic quantum number, m_l, determines the orientation of the orbital in space. The spin quantum number, m_s, describes the spin of the electron and can only be represented by the values, +1/2 or -1/2(Sharma, A., Schulman, S. G., 1999).

Upon excitation with a photon, an electron goes to a higher energy state and maintains its original m_s value, the spin of that electron is still paired with the one left in the ground state and the total angular momentum is zero, S=0 therefore the multiplicity (2S+1) equals one. When multiplicity equals 1 the excited electron is in the singlet state. Fluorescence occurs when an electron is excited to a singlet state and radiatively relaxes down to the ground state. This process is short-lived, usually 10^{-9} to 10^{-7} seconds (Sharma, A., Schulman, S. G., 1999).

If an electron is excited and has the same spin quantum number as the lone electron left in the ground state then the spin direction is parallel and the total angular momentum is equal to one and the multiplicity (2S+1) equals three. When the multiplicity equals three, the excited electron is in the triplet state. Phosphoresce occurs

when an electron enters an excited triplet state and radiatively relaxes down to the ground state. This process is much longer comparatively ranging from 10^{-5} to several seconds. Any condition that inhibits radiationless relaxation, lower temperature or a rigid medium, increases the amount of observable phosphorescence. Phosphorescence in solutions is observed less often than fluorescence mainly because of the non-radiative competing processes of collisional deactivation, quenching, photochemical reactions and other energy transfer process. Competing with both fluorescence and phosphorescence are several non-radiative processes including internal conversion and vibrational relaxation (Sharma, A., Schulman, S. G., 1999).

Figure 1. A Joblonski diagram of the processes that result in luminescence.



Source: Sharma and Schulman (1999)

When a molecule absorbs a photon of ultraviolet or visible wavelength, an electron is promoted to a higher energy state. This excited electron can return to the ground state through several processes. Luminescence occurs when this relaxation process results in the emission of a photon. If the electron radiatively transitions from the first singlet state back to the ground state then the emission of this photon is called fluorescence. Most observable luminescence from organic compounds comes from the excitation of an electron in a π orbital. If the electron radiatively transitions from the first triplet state to the ground state then the emission of this photon is called phosphorescence. An electron enters the first triplet state after an internal conversion from the excited singlet state. Because the transition can end on any one of the vibrational levels of the ground state, the phosphorescence band itself reflects the ground state of vibrational levels (Ingle, J. D., Crouch, S. R., 1988) (Schenk, 1973).

The excited electron may return to the ground state via non-radiative processes of internal conversion or vibrational relaxation. Whenever a non-radiative relaxation is energetically preferred over a radiative process the total amount of photons emitted by the sample will be reduced. The relationship between exciting photons and emitted photons is described as the quantum yield (Φ).

Fluorescent intensity at a specific wavelength is directly proportional to the number of photons absorbed. The non-radiative processes of intersystem crossing and

internal conversion compete with fluorescence for transition of the lowest excited singlet state electron and therefore not all potentially fluorescent molecules will return to the ground state by fluorescence. The amount of the excited molecules that fluoresce is called the quantum yield (Ingle, J. D., Crouch, S. R., 1988). Quantum yield represents the efficiency of the fluorescence emitted. The following equation states the relationship between fluorescence intensity and quantum yield (Guilbault, G. G., 1990).

$$F = [P_o(1- e^{-\varepsilon bc)}] \Phi \qquad \text{Equation 1.}$$

Where F is the fluorescence intensity, P_o is the source intensity, ε is the molar absorptivity, b is the path length, c is the concentration and Φ is the quantum yield. Guilbault states that when Eq. 1 is subjected to a McLaren (sic) expansion, the relationship between fluorescence intensity and concentration is linear when fluorophore concentrations is low and when $\varepsilon bc < 0.05$. This linearity is represented by Eq. 2.

$$F= [K\Phi P_o] \varepsilon bc \qquad \text{Equation 2.}$$

At higher concentrations, quenching causes deviations from linearity. Therefore, fluorescence spectrophotometry is a useful quantitative technique for concentrations within the linear range. Rigid structures have a much higher quantum yield than

compounds that are not rigid due to the inhibition of collisions that result in non-radiative relaxation and therefore will have a larger range of fluorophore concentrations that are linearly related to fluorescence intensity (Sharma, A., Schulman, S. G., 1999).

Fluorescence spectrometry is much more sensitive and selective than UV-Vis spectrophotometry. This makes it a very valuable technique for the analysis of very small concentrations (Schenk, 1973). Fluorescence intensity and concentration have a linear relationship only when the total absorbance of the system is below 0.05 absorbance units as measured on a UV-Vis spectrophotometer. Above this absorbance the relationship begins to plateau and could actual decrease due to the increased likelihood of solute-solute interactions.

Polycyclic aromatic hydrocarbons are highly fluorescing compounds. Polycyclic aromatic hydrocarbons (PAHs) contain the rigid aromatic structure necessary to inhibit radiationless relaxation that competes with fluorescence (Sharma, A., Schulman, S. G., 1999).

2. Effect of substituents

Any compound that allows the correct electronic transitions may fluoresce. Compounds with rigid aromatic rings are strong absorbers and are much less likely to

return to the ground state via non-radiative means, however not all aromatic systems behave in the same manner. Electron-donating groups (e.g. NH_2) bound to aromatic rings can increase fluorescent efficiency while electron-withdrawing groups (e.g. Cl^-) may quench fluorescence (Sharma, A., Schulman, S. G., 1999).

3. Effect of concentration

The same compound or mixture of compounds may exhibit differently shaped spectra at different concentrations. Shifts of the peak wavelength maxima to longer wavelengths are referred to as "red shifts." Red shifts occur at higher concentrations and not only alter peak maxima, but may result in changes in peak shape. As solute-solute interactions increase it is possible for excited molecules to aggregate with ground state molecules producing an excited dimer. This excited dimer could relax to the ground state non-radiatively, essentially quenching the fluorescence from the excited single molecule. If the excited dimer relaxes radiatively, the luminescence will be at longer wavelengths than that from the single excited molecule. This aggregation affects the shape, position and intensity of the resultant fluorescence (Sharma, A., Schulman, S. G., 1999).

Changes in the position and shape with concentration of the fluorophore are due in part to self quenching and self absorption. Self quenching occurs when energy is transferred via the collision between excited molecules. This process does not result in radiation. Because of the increased likelihood of collision, self quenching increases with

concentration and contributes to deviations from the linearity of Beer's law. At higher concentrations there is an increase in solute-solute interactions. As it does in absorbance spectroscopy, an increase in these interactions causes deviations in the linearity between concentration and intensity of fluorescent light (Sharma, A., Schulman, S. G., 1999). This study evaluated the use of chromatographic and gravimetric analysis to establish concentration. Proper concentration determination would ensure that all spectral differences and similarities seen in a comparison will be attributed to different sample composition and not different concentrations of the same composition.

Literature review

1. Early Work

Early work by the U. S. Coast Guard in the 1970's was successful in identifying the source of spilled oil using the complementary methods of fluorescence spectroscopy, IR spectroscopy, thin layer chromatography and gas chromatography. Each of these techniques is sensitive to different components in the sample. A multi-instrument approach is thorough but time consuming (Curtis, 1977).

2. SSE and VSSE

The first fluorescence spectra were made by either by keeping a constant excitation wavelength and scanning the emission wavelength range, or by keeping a constant emission wavelength and scanning the excitation wavelength range. Synchronous scan excitation (SSE) was a significant advancement. Both the excitation wavelength and the emission wavelength are scanned synchronously at a fixed wavelength interval ($\Delta \lambda$). The SSE technique usually results in more detailed spectra and therefore increased the discriminating power of fluorescence spectroscopy.

J.B.F. Lloyd addressed the evidential value of luminescence of engine oils and similar materials using synchronous scan excitation and emission fluorescence (SSE).

Lloyd was able to differentiate among samples with high molecular weight with the SSE technique (Lloyd, 1971, Part I, II, III).

SSE has been a very popular technique in the forensic analysis of transfer evidence. Rubber bumper guards and petroleum lubricants from sexual assaults were characterized by Blackledge (Blackledge 1980, 1983).

Pharr, McKinzie and Hickman used SSE to characterize gasoline, kerosene, diesel oil, asphalt and fuel oil in organic and aqueous extracts of ground water. They claimed this characterization is a "fingerprinting" technique. I find this terminology ill-fitting to describe the categorization they were successful in achieving. Any technique made analogous to fingerprint analysis should be an individualizing technique (Pharr et. al. 1992).

Patra and Mishra used SSE to classify diesel fuel, gasoline and kerosene. They actually induced the red shift seen with concentration dependent samples to characterize these materials and increase the discrimination of the technique. The wavelength shifting that the researchers used to characterize their samples is precisely why it is so important to establish a concentration for a proper comparison of samples in this study. If identical materials of different concentrations generate spectra of different shape and intensity false exclusions are probable (Patra et al, 2001).

Variable separation synchronous excitation (VSSE) was developed by Kubic, Lasher, Dwyer and Sheehan in 1983. This technique differs from SSE in that the $\Delta \lambda$ is not fixed. This advancement enabled the user to produce any cross-section of a three-dimensional total fluorescence plot between 45° and 90°. With multiple scans at different angles the three dimensional plot could be constructed. Using the VSSE technique, the researchers were able to differentiate between 61 new motor oils and 45 used motor oils, their results were presented in a two-part publication (Kubic et. al . 1983).

3. EEM and contour plots

When computers became the rule rather than the exception in data collection, three-dimensional fluorescence data representation was simplified. The three dimensions of excitation wavelength, emission wavelength and fluorescence intensity are referred to as an excitation-emission matrix (EEM). The EEM can be represented in two dimensions as a contour plot.

Early work with EEMs was done by Freegarde, Hatchard and Parker. They investigated the use of contour plots from fluorescence spectral data to differentiate oils and were successful in distinguishing among nine samples (Freegarde et. al. 1971).

In 1989 Siegel and Cheng were able to differentiate between samples of mid-range petroleum distillates, which appeared to be identical with gas chromatography, using 3D fluorescence plots (Siegel, et. al. 1989).

In 2006, Holbrook et al. at NIST investigated the effect of different corrections made to EEM spectra. The corrections significantly improve intra-laboratory data comparisons. Instrumental bias varies among instruments. This type of bias may result in "systematic errors in measured fluorescence intensity caused by the wavelength-dependent output or response of individual instrument components, such as excitation lamps, monochromator gratings, and detectors" (Holbrook, 2006). In order for laboratories to compare data collected on different instruments this instrument dependent bias needs to be corrected. Other researchers have addressed these corrections on the Varian Cary Eclipse (Holbrook, 2006) (Hall, Clow and Kenny, 2005). Since all fluorescence spectra were collected on the same instrument these corrections are not necessary for this feasibility study. The light source in the Varian Cary Eclipse is a xenon flash lamp. Since a flash lamp is only illuminated in very short period of time it has a much longer useable lifetime and is not prone to source decay. If future work aims to create a comparable data set, the 2006 Holbrook work should be consulted to inform data collection and processing.

4. Low Temperature Fluorescence Spectroscopy

Spectra collected at liquid nitrogen temperatures may show phosphorescence as well as fluorescence therefore it is most accurate to describe all low temperature work as luminescence spectrometry (Fortier, 1978).

Fortier and Eastwood, pioneers in low temperature luminescence, used this technique to differentiate among different classes of fuel oil. They noticed an increase in spectral structure and observable phosphorescence at 77K. Subtle spectral details were enhanced at liquid nitrogen temperatures. This increase in detail arises from the lack of collisional broadening and other non-radiative relaxation mechanisms that are hindered in the rigid, frozen glass. They determined that the optimum concentration for analysis is 10 to 20 ppm. This concentration gave sharp spectral structure with a good signal-to-noise ratio. These researchers, along with Hendrick, in a later article recommend the combined use of low temperature luminescence and synchronous scanning to differentiate among very similar oil samples (Fortier, 1978) (Eastwood, 1978).

In 1983, Kubic, Lasher and Dwyer, used low temperature luminescence and with variable synchronous excitation fluoremetry (VSSE) to distinguish among 61 automobile motor oils. They coupled the low temperature spectral data with room temperature spectal data to obtain complete differentiation among engine oils (Kubic, et al 1983).

In a 1998 Analytical Chemistry review article, Soper, Warner and McGown note that the publications regarding low-temperature luminescence have slowed but progress has been made in the applications of online detection in capillary electrophoresis to distinguish structurally similar analytes (Soper, et. al. 1998).

A 2006 review article compiled the literature from January 2004 to December 2005. The authors site advances using LEDs in time-resolved fluorescence of samples contaminated with crude oils, novel fluorescence sensors have been developed for the analysis of biological and chemical warfare agents, and numerous multivariate statistical analysis techniques are being applied to luminescence data. Much of the current research in the field of fluorescence spectroscopy is striving to make this technology more portable so measurements can be taken in the field. Portability is especially important to environmental chemists and hazardous material responders who work "in the field" and need fast but accurate results (Fletcher, et. al. 2006).

5. Other instrumental techniques

The only study to focus specifically on automotive chassis residue was conducted by Zieba. Zieba used IR spectrophotometry to identify the specific lubricating oils in the samples. She was most successful with fresh oil samples and less so with the undercarriage residues. She observed spectral difference among the undercarriage residue samples but could not determine if these differences were due to sample

composition or random errors or poor reproducibility of the technique. Her results show that significant changes to the class characteristics of the unused oils occur during use. Changes in lubricant chemistry brought on by mechanical and thermal stress caused observable differences in the IR spectra of the samples (Zieba, 1985).

In 2007 Reardon and his research team used high temperature gas chromatography-mass spectrometry to characterize new and used motor oils. PAH presence was investigated using extracted ion profiling and not chemical extraction. The percentage of aromatic compounds increased with the degree of oil wear. Of the different brands and grades, 32 of 34 samples were distinguished. Of the dipstick swabs 26 of the 30 samples were distinguished. All differentiation was done with visual examination of the smoothed chromatograms. The Reardon study shows that there are measurable differences in used motor oils (Reardon et. al. 2007).

To aid analysis of a more common forensic evidence type, Petraco, Gill, Pizzola and Kubic investigated the usefulness of multivariate pattern recognition procedures to distinguish among 20 liquid gasoline samples collected during casework. Their work showed that these samples could be differentiated using canonical variate analysis, orthogonal canonical variate analysis and principal component analysis with varying dimensionality requirements (Petraco et. al. 2008).

6. Sample Preparation

Kershaw and Fetzer developed an extraction procedure to analyze coal liquids by fluorescence spectroscopy. They fractionated coal liquids into oils, asphaltenes and pre-asphaltenes. Oils are soluble in n-pentane, asphaltenes are soluble in toluene and pre asphaltenes are soluble in pyridine. Pinero-Iglesias *et. al.* compared Soxhlet, ultrasonic and microwave assisted extraction techniques for the extraction of PAHs from diesel particulate matter using a standard reference material from NIST (SRM 1650). Extraction of PAHs from these types of particulates can be difficult because they form at the same time as the particles and can be adsorbed into their internal structure. The researchers found that the ultrasonic, microwave and Soxhlet extractions all had comparable recoveries of the individual PAH compounds (Kershaw et. al. 1995) (Pineiro-Iglesias et. al. 2002).

8. The Material - Automotive undercarriage residue

Automotive undercarriage residue is a complex mixture that has multiple contributing sources including motor oils and other lubricants, asphalt particles, tire particles and exhaust particles. All of these sources contain fluorescing compounds, particularly polycyclic aromatic hydrocarbons (PAHs) (Rogge, et. al 1993) (Pineiro-Iglesias et. al 2002). Logic dictates that the residues on the lowest parts of the automotive undercarriage are most likely to be transferred when the underside of an automobile comes in contact with a person or object.

Motor oil is used to inhibit metal-on-metal contact on engine parts. Motor oil is refined from crude oil and comes from the high boiling point fraction of crude oil. The base stock of motor oil comes from the lubricating portion of crude oil. This refined product contains additives to improve its performance as a lubricating agent. These additives include thickening agents, pressure additives, antioxidants, detergents, alkaline components, rust inhibitors, pour-point depressants and antifoaming agents (Motor Oil Guide, 1971) (Wilkinson, 1992). The Society of Automotive Engineers (SAE) assigns grades to motor oils based on viscosity. Some oils have two grades that reflect a changing viscosity with temperature. When stressed during use by high temperatures and mechanical movements, new compounds are formed through oxidative and other processes. These new compounds change the fluorescing characteristics of a motor oil, making the fluorescence spectrum on an oil a dynamic pattern (Kubic et al. 1983).

Road dust particulates come from many sources including vehicle exhaust, brake lining particles, road top particles, tire wear debris and settled aerosols from local combustion of fossil fuels. Rogge *et. al.* studied the organic contribution of all but the last contributor in this list and found polycyclic aromatic hydrocarbons present in all material types (Rogge et. al. 1993).

Regardless of the contributing source to the automotive undercarriage residue, only those compounds that contain fluorophores will contribute to the total fluorescence spectrum. A fluorophore is a functional group in a molecule that after photon excitation allows for the proper electronic relaxation to the ground state. The main fluorophore that will contribute the fluorescence spectrum of each sample is the aromatic ring.

Automotive undercarriage residue has multiple contributors. Of particular importance are those contributors which are dynamic in nature; the more dynamic the source, the greater the chance of individualization.

9. Importance of Concentration

It is important that a concentration of fluorescing compounds is established before final spectral characterization. Both intensity of luminescence and shape of the spectrum will change with concentration. It is imperative, for two reasons, that the concentration of the samples be established. First, comparisons of two samples with the same fluorescing compounds but different concentrations may results in a false discrimination if smaller secondary and tertiary peaks are not observed in the less concentrated sample. Second, the fluorescence exhibited by the detected compounds may shift to longer wavelengths at higher concentration. This shift may also result in false discrimination when comparing two samples of very different concentration but of common origin. False discrimination

in the method could result in false positives and false negatives if the method is applied to a questioned sample and a sample of known origin.

Some researchers have monitored and used the red shift as a way to characterize samples. Patra and Mishra investigated this concept to differentiate among different petroleum products. In their study they wanted to observe the red shifting to characterize the compounds (Patra et al 2001). Since individual compounds may not be identified, the total concentration of the compounds will be determined by measuring the total integrated area of the absorbing compounds resolved by liquid chromatography or by the mass of the extracted residues.

Methods

1. Sample Collection

Ten motor vehicles were included in this study. All ten were passenger vehicles, either sedans or sport utility vehicles, of various years, makes and models. Five undercarriage locations on each motor vehicle were sampled, including the right and left front ball joints on all vehicles along with three additional locations as detailed in Table 1.

Known samples have a naming scheme that reflects their original source. The generic name is "##X" where #1 equals the origin vehicle, #2 equals the origin vehicle location and X equals the known set it came from (A, B, C). For example, sample name 21A indicates that this swab came from car 2 (Ford Bronco II XLT), location 1(right ball joint) and is from known set "A."

Samples were taken with sterile cotton swabs and stored in labeled screw-capped test tubes. Each location was swabbed five times creating 5 sets of 50 samples. Additional samples of used motor oils were collected from the dipstick of each vehicle in the study. These liquid samples were used for instrumental method development due to the ease of making solutions of known w/v concentrations. These samples were not used in the known sets because they would not be representative of transferred materials as they are found on the underside of a motor vehicle. Instead, swabbed samples were taken from the bottom of vehicle oil reservoirs. Residues from the exterior of the reservoir, while they may contain used motor oils that have seeped out of the interior of the oil reservoir, they also contain road particulates and other debris. It is this exterior-pan

material that is more likely to be transferred when a person or item comes into contact with the underside of a motor vehicle.

From the five swabs taken at each location, three sets were used as the identified known samples, one set was used for extraction and instrumental method development and one set was re-labeled to produce samples of unknown origin. The unknown sample set was re-labeled by Kate Grimley, who recorded the origin of each unknown and sealed these results in a signed and dated envelope. Additionally, Ms. Grimley chose a numbering scheme that was random with respect to the origin naming scheme. Each unknown name begins with the letter "M" and is followed by a two digit number. I arbitrarily selected, without replacement, ten of these relabeled vials to be the unknowns in this study.

There were observable differences between the residue colors, textures and ease of transfer from vehicle to vehicle. In general, older vehicles yielded greater quantities of transferable undercarriage residues which were more greasy than the residues from younger vehicles. Newer vehicles, especially the BMW 330xi, yielded less material per swab and this material was grittier and less oily than that found older cars. This implies that the tendency to transfer oils and other lubricants may be a function of age, use and vehicle design.

2. Extraction Procedure

The Kershaw and Fetzer three-solvent extraction scheme was used for this study. Three fractions, oils, asphaltenes and pre-asphaltenes, were extracted from each swab using ultrasonication solvent extraction with pentane, toluene and pyridine respectively. The extraction took place inside the same screw-capped test tube used for swab storage.

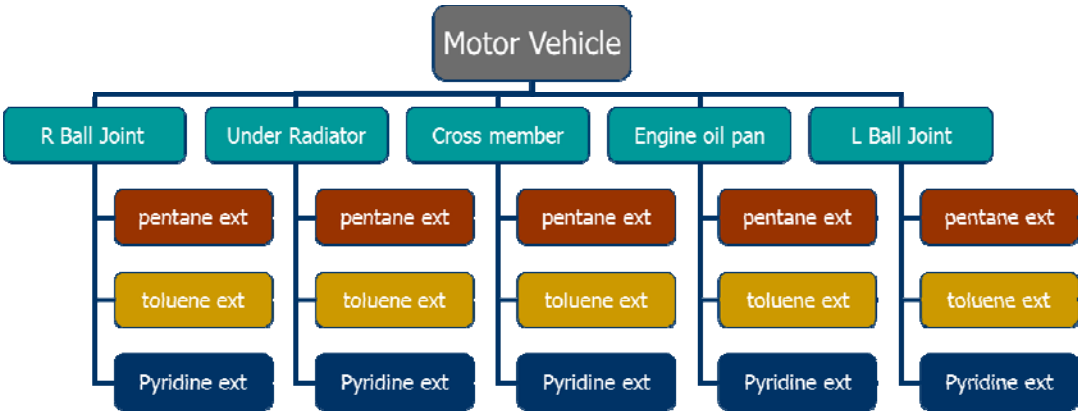
The extraction technique is summarized in Table 2 below:

Table 2. Extraction Method

Extraction volume	2 aliquots of 2mL each
Temperature	Pentane – 30 ºC Toluene – 60 ºC Pyridine – 60 ºC
Sonication time	30 minutes each aliquot (1 hr total)
Centrifugation time	20 minutes for the combined aliquots.

The total sampling scheme is summarized in the Figure 2.

Figure 2. Total Sampling Scheme - Flow Chart of Sampling and Extraction Scheme for a Single Motor Vehicle



After extraction, the two aliquots were combined and filtered with successive 0.42 micron and 0.22 micron nylon syringe filters to reduce turbidity. A turbid solution can contribute to undesirable Rayleigh-Tyndell (RT) scattering. RT scattering inhibited spectral details in previous work. (Purcell 2002) After filtration, extracts were centrifuged for 20 minutes and then were gently evaporated at room temperature for at least eight hours in preweighed aluminum weighing dishes. Each dish mass was taken in triplicate and averaged. The average pre-residue mass was subtracted from the average post-residue mass to determine the actual residue mass. Residues were then quantitatively transferred to a 5 mL volumetric flask using successive washes of the dilution solvent. The concentration in w/w ppm for each undiluted solution of pentane extract was calculated using the equation below:

$$C = (g_{residue}*1000)/(\rho_{solvent}*V_{flask}/1000) \qquad \text{Eq. 2}$$

Where C equals the concentration in ppm of the undiluted solution, $g_{residue}$ is the average mass of the pentane extract residue, $\rho_{solvent}$ is the density of the solvent[1] and V_{flask} is the volume of the volumetric flask.

The undiluted solution concentrations of known samples ranged from 9600 ppm to 22 ppm. The triplicate knowns from 22A were run at no dilution, 200 ppm, 100 ppm and 50 ppm at three excitation wavelengths, 220 nm, 230, nm and 290 nm. The spectra from the samples at 100 ppm concentration produced the best results with the relative

[1] Acetonitrile for the pentane extracts and methylcyclohexane for the toluene and pyridine extracts.

intensities of each lambda max at each excitation wavelength showing agreement among the triplicate samples from the same motor vehicle location. The undiluted solutions from the triplicate samples did not exhibit the same relative ratio of fluorescence intensities for the lambda max peaks at each excitation wavelength. These variations in spectral shape and relative intensity could be due to red shift observed at higher concentrations. This result favors dilution to a common concentration over no dilution of the extract solution. This result is in agreement with previous work by Eastwood and Kubic, who in separate studies recommended bringing all solutions to a common concentration prior to spectral data collection.

Previous researchers have used a variety of sample concentrations for the fluorescence analysis of oils. Eastwood , Siegel and Kubic independently recommended 20 ppm for direct analysis of oils. Purcell, whose work was also on motor vehicle undercarriage residues used a range of 10-100 ppm. The trials done using known 22A also recommend using a concentration at or close to 100 ppm. This may differ from previous work on oils since the automotive residue may contain many more material types than straight motor oil (e.g. road dust, diesel particulates). The 100 ppm concentration is based on total residue weight and a smaller portion of that residue contributes to the overall fluorescence of the sample. Any extract solution that was at 100 ppm or lower was left undiluted. The same sample naming scheme was expanded to

represent the extract type. The letter P, T, or Y was added to the end of each sample name to denote the pentane, toluene or pyridine extract respectively.[2]

Three extraction system blanks were run. Clean swabs were subjected to the entire extraction procedure including sonication, centrifugation, filtering, evaporation and reconstitution in a solvent. The blank extracts were run on the Cary Eclipse using the room temperature fluorescence excitation emission matrix parameters and low temperature emission scan fluorescence parameters. The resulting fluorescence spectra show that none of the materials used for sample preparation (i.e. swabs, glass test tube, filters or solvents) contributed any fluorescence to the extracted sample. This illustrated in figures 3-5. Note that there is no 2nd order Rayleigh scatter exhibited in figures 3-5 because of monochrometer filter settings.

[2] Sample 22AT is the reconstituted toluene extract residue from vehicle 2 (Ford Bronco), position 2 (left ball joint), known set A.

Figure 3. Pentane Extraction Blank

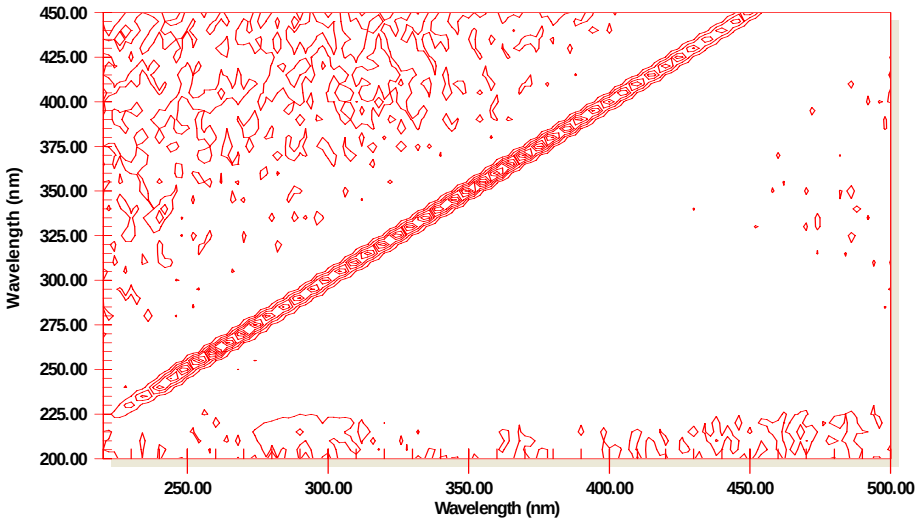


Figure 4. Toluene Extraction Blank

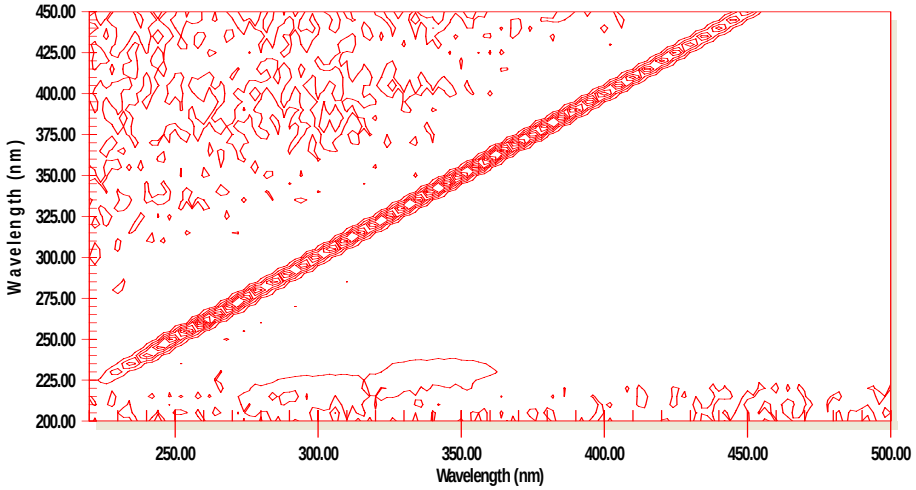

Figure 5. Pyridine Extraction Blank

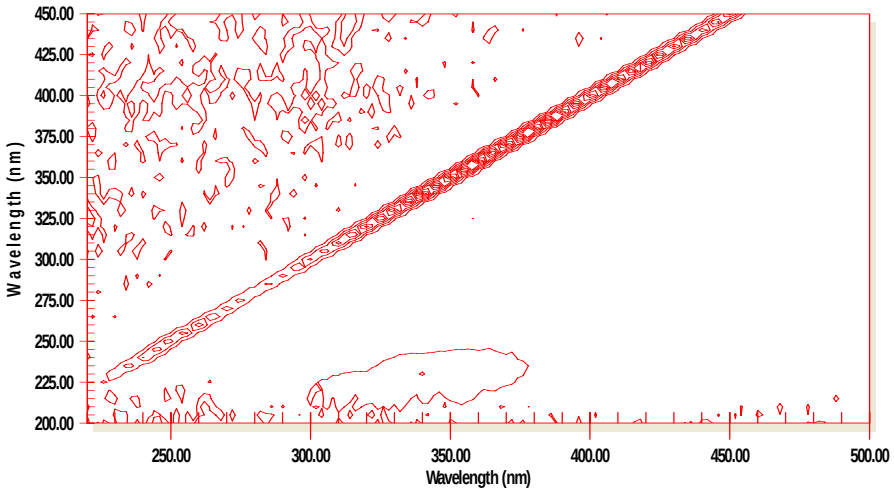

Acetonitrile and methylcyclohexane, the two solvents used for residue reconstitution and fluorescence analysis were run as blanks. There was no contribution to the observed fluorescence spectra from these two solvents. This is illustrated in figures 6 and 7. Please note that figures 6 and 7 were collected at a different emission filter setting than figures 3-5. The open setting resulted in the collection of 2nd order Rayleigh scatter.

2. HPLC Method Development

Since the concentration of the fluorescing compounds in each sample will effect the peak intensity and number. It was important to determine a suitable method to create extracts of similar concentrations. Purcell's work used calculated residue weights diluted to a constant volume to create extract solutions which were then diluted to common concentrations. While he was successful at creating solutions with a common ppm

concentration, this was based on weight of all compounds extracted, and the true concentration of fluorescing compounds remained unknown. One of his recommendations for future work included using chromatographic data, specifically peak areas of a compound common to all extracts in that class to base concentration calculations on.

It was determined that HPLC was the preferred chromatographic technique. There were established methods, solvent systems and column types for the separation of polyaromatic hydrocarbons and if asphaltenes, much larger molecules with thermally labile peripheral alkyl groups, were extracted in high concentrations, this method would be preferred to gas chromatography. Additionally, HPLC has a wider variety of detector types available. It was determined that a fluorescence detector would be the best suited for this task.

Using a fluorescence detector would ensure that the compounds used to adjust the concentration exhibit fluorescence and directly influence the fluorescence excitation-emission spectra. A review of the several different commercially available fluorescence detectors was done. Funds were available through a grant from the Borough of Manhattan President's Office. I reviewed the commercially available units and obtained quotes from vendors. All necessary paperwork was submitted to the city representatives to complete the purchase. After multiple communications with representatives of the City of New York purchasing department, it became clear that the procurement process

and the hurdles encountered would delay the project timeline so much so that it became prohibitive to proceed with procurement for this study. This was indeed the case as the equipment was actually delivered in November 2010 and installation has just been completed as of this writing; almost two years after the purchasing process began. Without the ability to procure a fluorescence detector for the HPLC instrument in-house, I decided it was best to proceed with UV detector already available and installed on the HPLC. The instrument used was a Shimadzu HPLC with a SCL-10A system controller module, SIL -10A auto injector, SPD-10A UV absorbance detector. All data was collected on a HP3396A integrator.

The first of three swab extracts (pentane) was evaporated to dryness, reconstituted and brought to 5 mL total volume in acetonitrile. These undiluted solutions were analyzed via HPLC. Peaks common to all three swab extracts from a single vehicle location were identified and their areas added to create a total peak area for each known. This method is similar to that used for compounds that were historically difficult to resolve such as PCBs (Butcher *et al*, 1997).

Historically, this quantification method has been used to quantify polychlorinated biphenyl compounds analyzed by gas chromatography. Most commercial PCB production was conducted by the Monsanto Corporation and marketed under the brand name Aroclor. Packed GC columns lack the resolving ability to separate the compounds in the PCB mixture. These products were quantified using the total peak areas of selected

Aroclor peaks resolved in the chromatogram. In the method employed for this project, the peaks identified as common to each triplicate sample are analogous to the Aroclor peaks selected to represent concentration of the entire PCB sample.

3. Solvent Incompatibility

The literature most strongly supported the use of a reverse phase system for polycyclic aromatic hydrocarbons detection by HPLC. However, the aqueous solvent system and the methylcyclohexane necessary for the low temperature spectral analysis are not miscible. Since both the investigation of using chromatographic techniques and the characterization of sample fluorescence at liquid nitrogen temperatures were important parts of this project it became necessary to find a compromise. Any extract residue that was reconstituted in acetonitrile would not be able to be analyzed at low temperatures and any reconstituted in methylcyclohexane would not be analyzed by HPLC. Of the three swab extracts, pentane, toluene, and pyridine, it was expected that the toluene and pyridine extracts, if they contain asphaltenes and pre-asphaltenes as recorded by Kershaw and Fetzer, would contribute the most fluorescing components due the preponderance of aromaticity, while the oils would contribute the least due to the preponderance of unconjugated compounds. I decided to analyze the pentane extracts with HPLC and UV detections to adjust concentrations with the oils extract while reserving the other two extracts for low temperature analysis.

Table 3. HPLC Method

Isocratic Elution[3]	10:90 H2O: ACN

The HPLC column used was a Supelco brand Supelcosil LC-PAH, 5 cm x 4.6 mm ID with 3 micrometer particles. The LC-PAH stationary phase is C-18. A guard column with the same packing material was used to prolong the life of the analytical column. Column performance was tested with three standard polyaromatic hydrocarbons listed in Table 4. Detector response linearity was tested with dilutions of phenanthrene and naphthalene in concentrations ranging from 0.019 µg /mL to 4.00 µg /mL and 0.23 µg /mL to 50 µg /mL respectively. The results are shown in Tables 6 and 7.

[3] Gradient elution was tested on dilute solutions of used waste oils. The instrument had difficulty returning to a stable baseline after the end of the gradient program. The isocratic program eliminated the baseline drift problem by maintaining a constant solvent system and ensuring complete elution of all injected compounds.

4. Cary Eclipse Instrumentation

All fluorescence spectral measurements were made on a Varian Cary Eclipse Fluorescence Spectrometer. It has a xenon flash lamp source and an extended range (200 nm – 900 nm) photomultiplier tubes, both sample and reference. Wavelength selection is accomplished with two grating monochrometers. The xenon flash lamp and signal processing technology makes the Cary Eclipse nearly immune to room light contamination. The Cary Eclipse was designed with the detector located at 90 degrees from the source. This geometry limits detection of unscattered photons from the source lamp. (Ingle, Crouch)

The Cary Eclipse software contains a validation function that tests the wavelength accuracy of the excitation and emission monochrometer and the spectral bandwidth accuracy of the excitation and emission slits.

Stray light is monitored by taking the ratio of the intensity of scattered light detected by the sample PMT at a wavelength which is at the very edges of the excitation wavelength (i.e. in the excitation wavelength is set to 350 nm this test will measure at 371 nm) The ratio must be between -0.0005 and 0.0005 a.u. to pass the test. The Raman band of water is measured at 350 nm and 300 nm and was used to test the sensitivity of the instrument. Wavelength reproducibility is measured by repeatedly measuring the wavelength at the 541.92 nm Xe lamp peak for 10 scans and calculating the difference between the extremes of the wavelengths measured. The difference must be less than 0.2 nm to pass. Wavelength accuracy is also tested using lines from the Xe source. Peaks must be within 0.5 nm of the line at 541.92 nm and 1.0 nm of the 260.54 nm line in order to pass. Initial execution of these validation tests show that the Cary Eclipse was performing within the desired parameters as set by the manufacturer.

Data Collection

Excitation Emission Matrix Room Temperature Fluorescence

One sample from each vehicle undercarriage location was selected for room temperature excitation emission matrix fluorescence spectral data collection. Table 8 shows the instrument settings for this data collection. The EEM spectra from known samples collected are listed shown in the Appendices C-E.

Table 8. Cary Eclipse Setting for Room Temperature Excitation Emission Matrix Data Collection

Excitation Start	200 nm
Excitation Stop	500 nm
Emission Range	220-600nm[4]
Data Step[5]	5 nm
Ex Slit	5 nm
Em Slit	5 nm
Scan Rate	1200 nm/min
Data Interval[6]	2.0 nm
Averging Time	0.1 sec
Ex Filter	Auto
Em Filter	Auto[7]
PMT	Medium (600 V)

[4] The emission range for EEM data went from 220-600. No peaks were observed past 400 nm. The scale was reset to 220-400 nm during data processing to improve the presentation of EEM spectral detail.

[5] In an excitation emission scan, the *Data Step* is the amount that the excitation monochrometer moves prior to the next scan. It is the distance between the slices that form the EEM.

[6] The *Data Interval* determines the size of the steps between each data point in the emission range.

[7] For the pentane and some of the toluene extracts, this filter was set to "Open." This setting resulted in the collection of secondary RT scatter at wavelengths from 440 nm and above. Data processing with the Excel macro removed these peaks. The emission filter setting "Auto" is recommended for future work.

1. Parameter Selection

The excitation wavelength range was chosen based on previous work with this sample type and with direct analysis of motor oils (Purcell 2002) (Fortier and Eastwood 1978). Most organic molecules fluorescence at excitations below 500 nm. (Schenk 1973) And since the majority of the fluorescence observed is expected to be from polycyclic aromatic hydrocarbons, this excitation range is sufficient to capture these data.

Slit widths for the excitation and emission monochrometers were chosen based on previous work (Purcell 2002). The spectral resolution would have been improved with smaller slits however, there was concern about losing information from more weakly fluorescing samples. Since this resolution was sufficient for successful sample discrimination and known-unknown association in a previous study and in this work, produced EEM spectra with sufficient detail to collect the main points of comparison (i.e., the excitation and emission wavelengths of the peak fluorescence) the same slit widths were adopted for room temperature data collection for this work.

Varian claims the Cary Eclipse is capable of scanning at speeds up to 24,000 nm/min without exhibiting peak shifts. However at such a high scanning rate finer secondary spectral features may be lost. Trials with sample 41A established that a scan rate of 1200 nm/min, when compared to a scan rate of 600 nm/min, would produce spectra with no peak shift from the slower scan rate and sufficient secondary spectral detail in an EEM. This is illustrated in the Figures 13 and 14 below. The EEMs of 41A at both 600 nm/min and 1200 nm/min exhibit the same number of peaks at the same positions and all secondary spectral detail is the same. Scan rate, averaging time and data

interval are all inter-related on the Cary Eclipse. When set to the 1200 nm/min the Cary automatically sets the data interval to 2.0 nm. At this interval the noise observed at excitation wavelengths below 225 nm was reduced.

A PMT settings of medium (600 V) and high (800 V) were tested on 17 samples of known origin from 6 different motor vehicle locations. For the room temperature data collection, the PMT setting at 800 V produced many fluorescence spectra with intensities that exceed the range of the PMT. This problem was not observed with at the 600 V setting.

The use of spectral smoothing, specifically Savitzy-Golay, was considered. Setting the instrument to smooth during collection would not have allowed the collection of the raw, unsmoothed data. Attempts to smooth after collection would be extremely time consuming. Each EEM is constructed with 60 emission scans and each would have to be separately opened, smoothed and then all 60 would be reassembled in a matrix. Considering that the main data points for the comparison of spectra, the emission and excitation wavelengths of the peaks, would not be improved with smoothing, it was decided that the collection of raw but noisier data was preferable to smoothed.

Figure 13. Known 41A at Scan rate 1200 nm/min

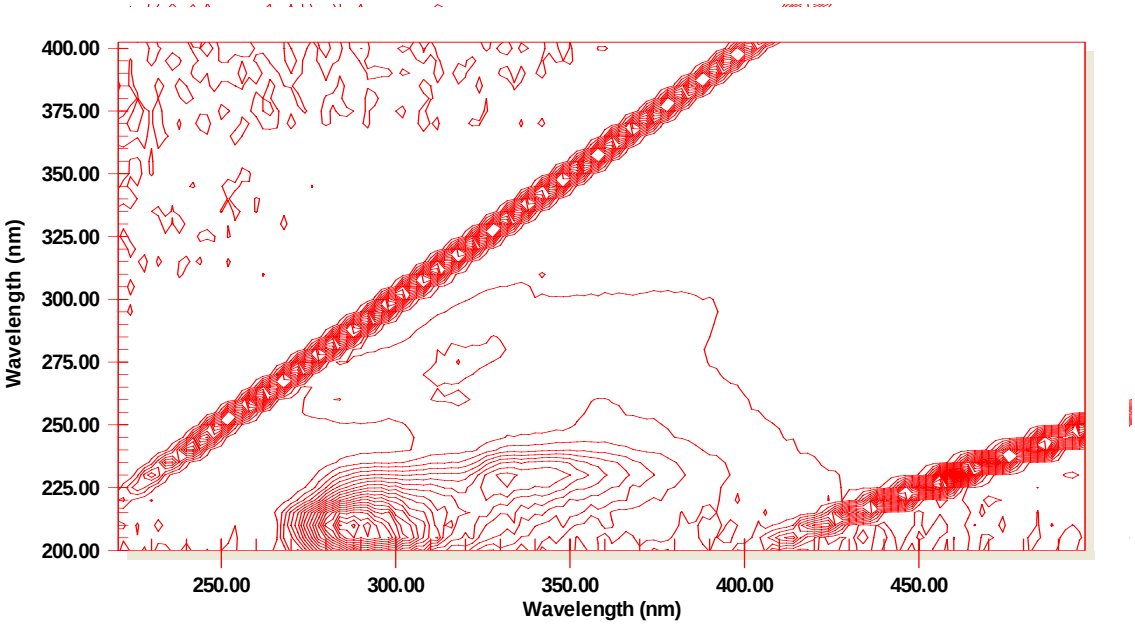

Figure 14. Known 41 A at Scan rate 600 nm/min

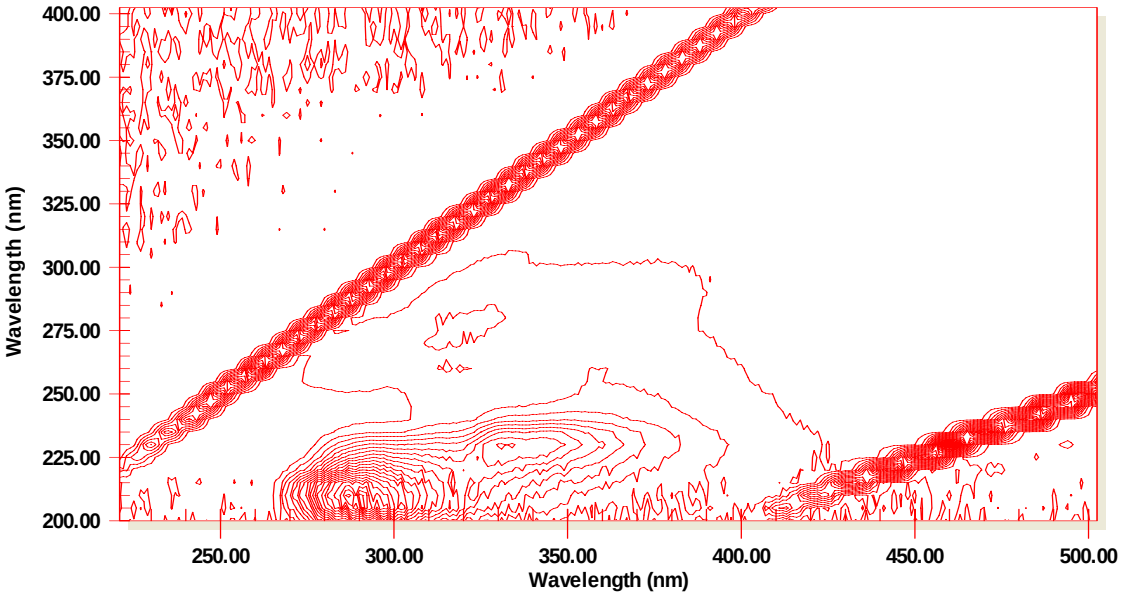


At the slower scan rate, and smaller data interval (1nm), figure 14 does exhibit smoother contour lines, especially in the excitation wavelength regions above 250 nm.

Below an excitation wavelength of 250 nm, the smaller data interval also captures more of the noise at this wavelength region were a xenon source is less intense. Since most of the peaks from these undercarriage residues samples occur at these low excitation wavelengths, the increased resolution provided by the smaller data interval did not outweigh the increased difficulty in finding peak maxima below excitation 250nm. Therefore, the faster scan at 1200nm with the larger data interval was preferred for the EEM data collection.

2. EEM Spectral Processing

The primary and secondary Raleigh Tyndall (RT) scattering observed and in previous work by Purcell was thought to be caused by turbid solutions. Turbidity can cause this type of elastic scattering because light is physically deflected from the small particles suspended in solution. However, the intensity of the RT scattering was relatively constant. Samples from the previous work were filtered once through 0.44 micron syringe filters and the results were normalized to the largest peak intensity. As a result the RT scattering looked very large on spectra that had very weak fluorescence intensity. Filter settings can eliminate collection of second order RT scattering. The emissions filter was sent to "Auto". These settings were used on most of the toluene extract solutions and all of the pyridine extract solutions. To generate accurate contour plots the RT scatter must be removed so that the Grams software does not include these peaks when scaling the contour slices. Contour plots are made by taking the total fluorescence intensity range and dividing it into a pre-determined number of sections.

The more sections the software is asked to create the more contour lines will appear on the plot. If the RT scatter is the most intense peaks in the data set, the actual fluorescence emission will be divided into less contour slices than the analyst may intend. This effect is most damaging for weakly fluorescing spectra that are more 'dwarfed' by the intense RT scattering.

A Varian representative sent an application development language (ADL)[8] program that was to stagger the starting wavelength on the emission monochrometers to avoid collecting any RT scatter. Instead of all emission scans beginning at the same wavelength this program purported to stagger the start wavelength of the emission monochrometer. For example, the first excitation wavelength 200 nm with emission scanning from 220 nm to 600 nm would collect no RT scatter because there was never a time when excitation wavelength = emission wavelength but when the excitation wavelength moved above 220 nm the emission scan would start at a longer wavelength (e. g. 240 nm) thereby cutting out the RT scatter. This program never performed as advertised. The file as-sent would not upload because of syntax problems. I edited the format into one readable by the ADL shell. After several more edits to the ADL code a single EEM spectra was collected successfully. However attempts to display this file as a contour plot resulted in repeated crashes of the Cary Eclipse program. These experiences

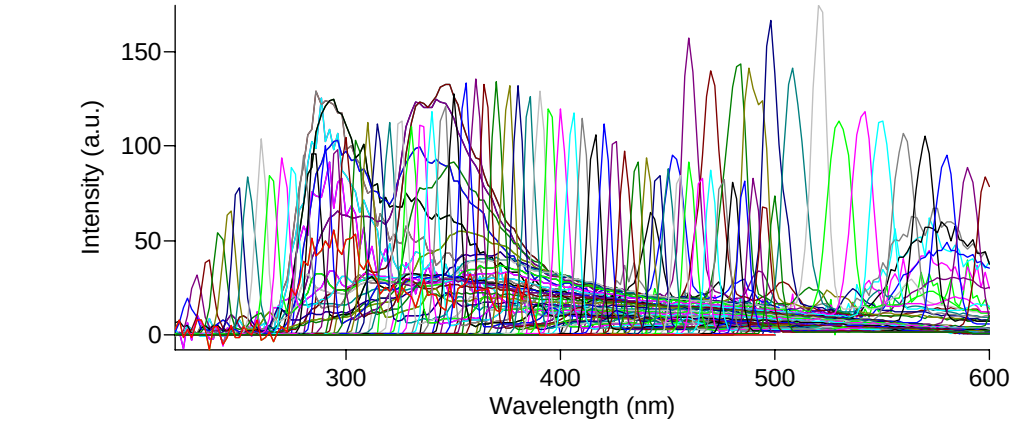
[8] The application development language (ADL) is a programming language, similar to BASIC, that is used by the Cary Eclipse software.

led to the decision to collect the EEM files without real-time efforts to avoid collecting RT scatter.

This scatter was removed post data collection by a customized Excel macro program. The excel macro is designed to replace intensity values with a zero value in key places where first and second order RT scatter is found. The macro deletes every intensity value where the emission wavelength is less than or equal to the excitation wavelength minus 5nm. Since fluorescence emission does not usually occur at wavelengths higher in energy than the excitation wavelength, no important spectral data is lost in this deletion. Any fluorescence due to the anti-stokes shift, where the emission is at shorter wavelengths than the excited radiation, will not be removed by this macro if it occurs at wavelengths 5 nm shorter than the excitation radiation. Peaks from anti-stokes shifting are usually much less intense than RT scatter peaks and are not necessary to remove from the data set because they do not overwhelm the spectral data.

This is repeated for intensity values at positions 2x the previous wave to delete 2nd order RT scatter. This had the largest impact on contours created from samples with weak fluorescence intensity where the RT scattering has the most obscuring power. The effect of this program is illustrated in Figures 15 and 16. Figure 16 shows that after removal of the RT scatter, three additional low intensity peaks are displayed by the contour plotting function.

Figure 15. 83BT Before Rayleigh-Tyndell scatter removal. Each color represents an excitation scan at a difference excitation wavelength.



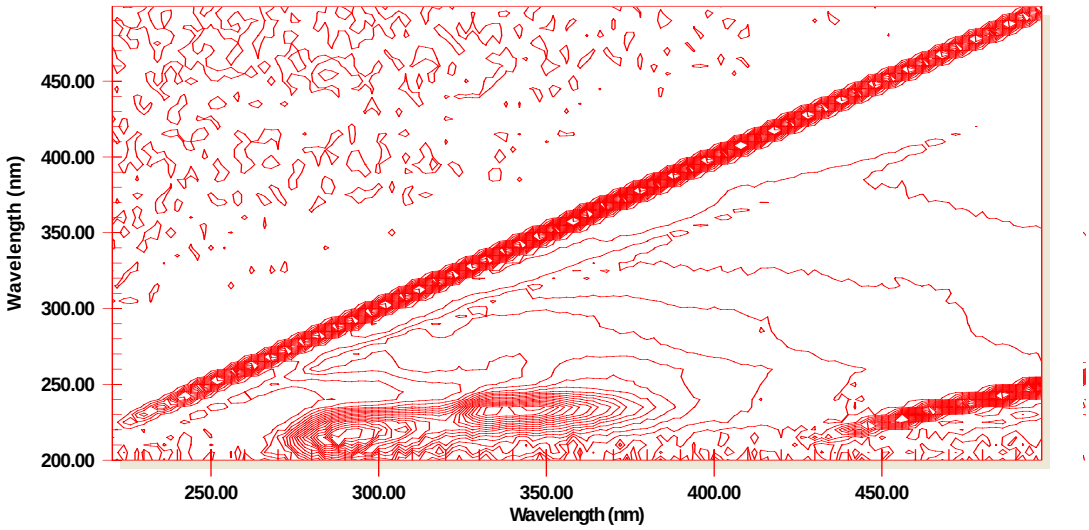


Figure 16. 83BT After Rayleigh-Tyndell Scatter Removal. Each color represents an excitation scan at a difference excitation wavelength.

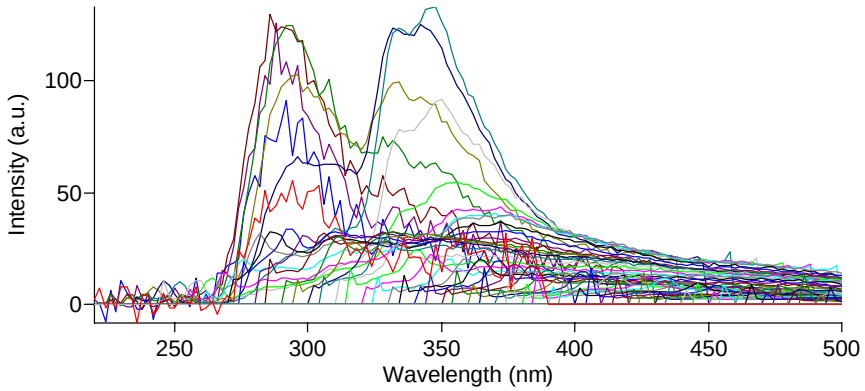

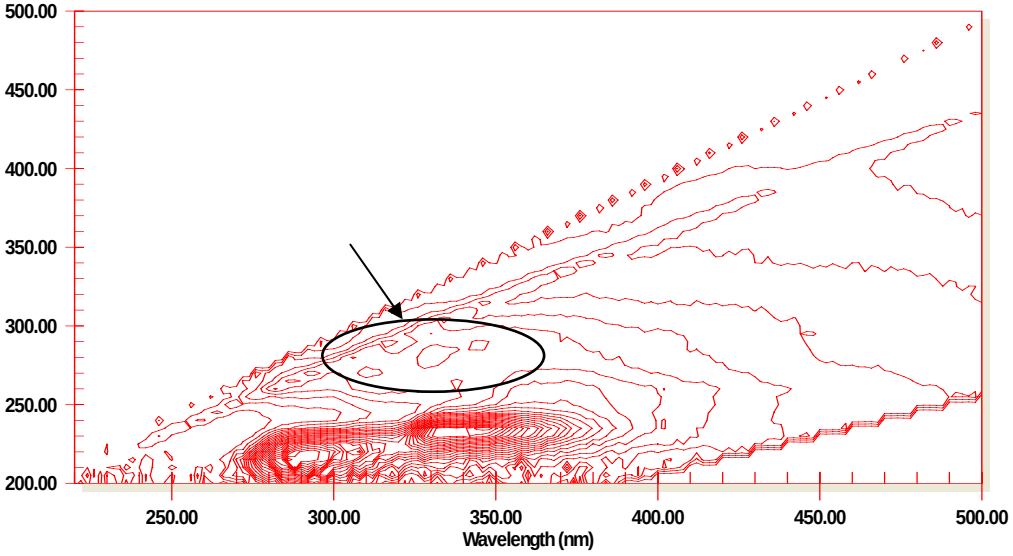

3. Low Temperature Fluorescence

Development of the Low Temperature Fluorescence Apparatus

In order to achieve the decreased temperatures needed to generate more detailed spectra I used an apparatus designed to freeze the solutions in liquid nitrogen temperature, 77K. There are several challenges associated with this process and that

must be overcome in order to generate useful spectra, most notably, maintaining frost-free sample windows and producing clear and crack-free frozen samples.

4. Apparatus

The original design supplied by Varian was inoperable. The Dewar itself had no cap and was to remain open to the atmosphere when filled with liquid nitrogen. This would not work as the freezing agent would evaporate before the completion of a single EEM, run which can take upwards of 20 minutes. Without a cap to support it, the sample tube was supposed to sit in the bottom of the Dewar and rest on the side of the reservoir resulting in a tube that was at an angle and other than normal to ground. Test scans showed that this angled tube resulted in increased Raleigh-Tyndell scatter that was most likely due to the excitation beam meeting the sample tube surface at an angle other than perpendicular.

5. Design Modifications

A cap similar to the Farand design was necessary to slow the evaporation of the liquid nitrogen and to position the tube normal to the excitation beam.

Figure 17. Farand Dewar cap with quartz-tipped glass sample tube.

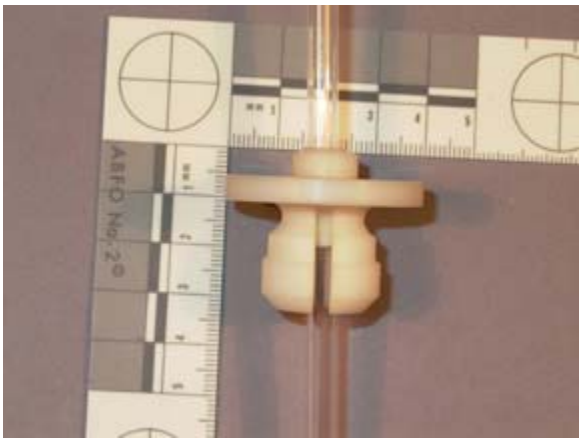

Figure 18. Farand Dewar cap top view showing vent holes.

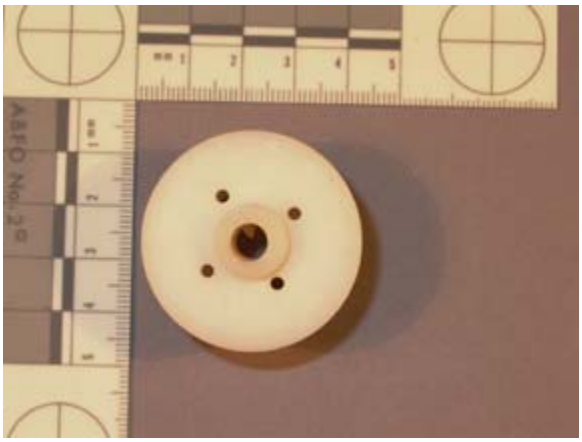


The Varian Dewar was taller than the top of the sample compartment and wider than the original Farand design[9]. To make room for this a new top was supplied with a hole cut in

[9] The Farand Dewar owned by Dr. Thomas A. Kubic is 4.3 cm OD while the Dewar supplied by Varian is 7.7 cm OD.

the top. This top was a solid piece and therefore the Dewar and the support apparatus had to be inserted into the instrument through the hole itself.

This was extremely awkward and eliminated any possibility of ensuring that the Dewar support and the quartz bottom aligned with the source. The sample tubes supplied were quartz NMR tubes with an extremely small inner diameter (3mm) and a height less than that of the Dewar itself. This limited the amount of liquid nitrogen allowable in the reservoir because it could not be higher than the top of the tube. In order to solve these issues a memorandum was drafted and sent to the vendor requesting the lid be split in two to and a cap for the Dewar. Photographs and dimensions of the original Farand cap and Dewar, measurements of the new Dewar and desired tube specifications and material preferences were sent to guide the production. Work proceeded once these modified products were delivered.

After adoption of the split lid, longer tubes and sample cap work continued on apparatus. One of the main differences between the original Farand design and the Varian design was that the Farand Dewar sat in an enclosed metal collar with inlet and exit ports for purging gas. Clearance between the collar and Dewar was not more than 5 mm. This reduced the amount of empty space around the container thereby requiring a slower stream of purge gas to ensure a dry environment. A dry environment is necessary because any moisture will freeze on the surface of the cold Dewar as white snowy ice; a

highly scattering beam-blocking coating. The better the vacuum in the Dewar walls the less likely this was to occur but it must still be avoided.

The Cary Eclipse has a large open sample compartment. While this is good for fitting in a variety of accessories it is not good for low temperature analysis. Extra space was reduced by introducing black paper-covered Styrofoam blocks to the sides of the container.

4. Final Design of the Low Temperature Apparatus.

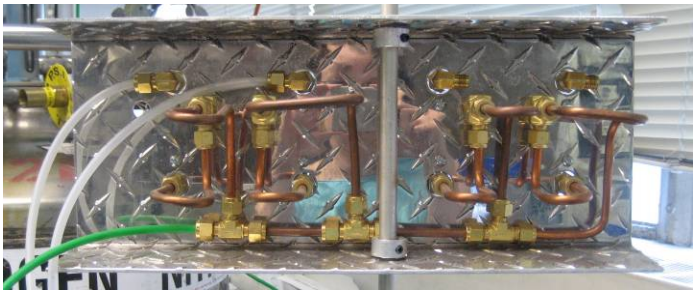
A series of modifications to the interior of the sample compartment were tested to allow for the driest environment with the slowest flow of dry N_2 gas. Determination of the necessary modifications was an iterative process. As each design element was adopted or altered, the relative humidity (RH) of the sample compartment was monitored using a relative humidity meter. Monitoring would begin with the sample compartment at equilibrium with the laboratory RH and continue as the flow of dry nitrogen gas was delivered from the flow meter manifold. RH data was collected once every minute until the sample compartment interior reached a stable baseline. These data sets were used to identify the sample compartment design that would allow for the fastest drop in RH and the lowest sustainable RH at equilibrium.

The final design of the low temperature apparatus include a quartz-tipped liquid nitrogen Dewar held in a fixed position by an adjustable frame. Two nozzles attached to the frame delivered a steady, but adjustable stream of dry nitrogen gas to the tip of the Dewar to prevent frost formation. The nitrogen gas was supplied by the headspace of the liquid nitrogen tank and the flow was regulated by a custom built manifold of flow meters.

Figure 19. Flow Manifold[10]

Front View

Back View

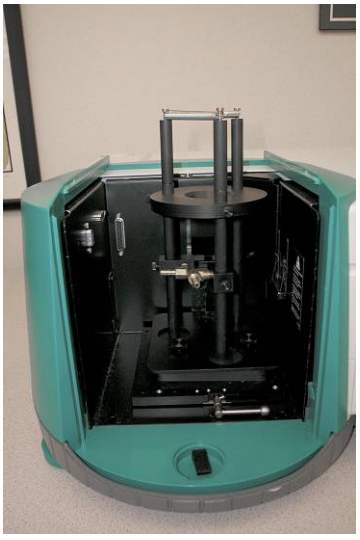


[10] As designed by Dr. Thomas A. Kubic and assembled by the author.

Styrofoam blocks, covered with black paper, were cut to fit the chamber shapes were used to limit the empty space in the sample chamber. All exterior seams on the instrument sample compartment were covered with masking tape to reduce the exposure to humid air. The Dewar was accessed through a split top with a black cap. This set-up allowed access to the Dewar bell to refill with liquid nitrogen and to remove and insert sample tubes without exposing the quartz sample tip to humid air.

Figure 20. Quartz Tipped Dewar

Figure 21. Cary Eclipse sample compartment with Dewar housing.



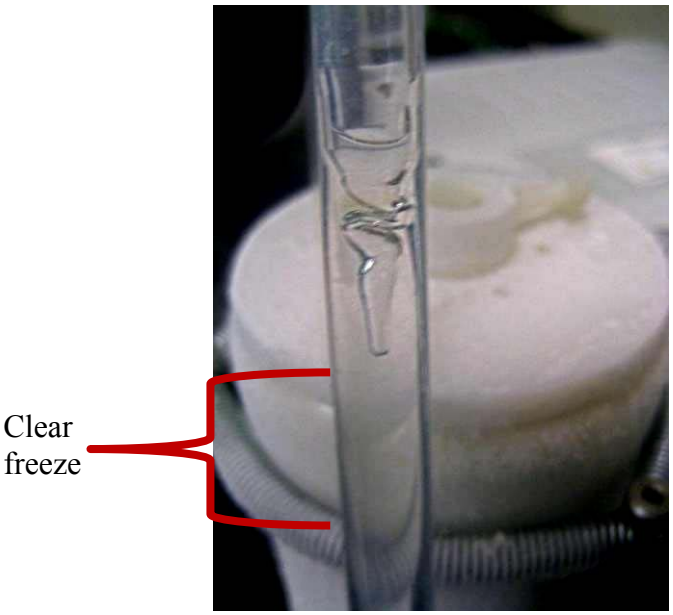
Despite all efforts to limit chamber humidity it was still necessary to keep the flow of dry nitrogen high (1L/min) and to monitor the sample chamber humidity with a relative humidity sensor with digital display. This final design would keep the quartz tip of the Dewar frost free for up to 10 hours and allow the user to do multiple quartz tube sample changes and liquid nitrogen refills. The illustration of this final design are shown in the figures below.

Figure 22. Modified interior for LT Fluorescence (Shown with cuvette holder, Dewar housing not pictured).

Figure 23. Operational View of Low Temperature Set-Up

Careful selection of sample solvent can protect against the effects of a highly scattering solid. Previous work by Kubic and Sheehan found that methylcyclohexane will freeze to a clear solid. When cooled slowly through gradual immersion, a clear frozen glass is obtained. This is shown in Figure 24.

Figure 24. Clear freeze of methylcyclohexane



The total data set for low temperature scans of the samples from known vehicle locations equaled 5,400 data files. The ensemble averaged scans (16 single scans of the same sample at the same excitation wavelength averaged automatically) at excitations 235 nm and synchronous scan at Δ 70 nm exhibited the most consistently intense spectra of all the low temperature data collected. Therefore, these two data sets were chosen to examine the usefulness of using spectral library searching for making correct origin associations among transferred vehicle undercarriage residues. Instrumental settings for low temperature fluorescence data collection are shown below in Table 9.

Table 9. Cary Eclipse Settings for Low Temperature Data Collection

Excitation Wavelengths for Toluene extracts (nm)	220, 235, 275
Excitation Wavelengths for Pyridine extracts (nm)	220, 275, 290
Delta setting for Synchronous Scanning	70, 105
Ex Slit	10nm Round
Em Slit	1.5 nm
Scan Rate	600 nm/min
Data Interval	1.00 nm
Averging Time	0.1 sec
Ex Filter	Auto
Em Filter	Auto
PMT	High (800 V)

Because a smaller emission slit was chosen for the low temperature scans, the PMT voltage was changed to High (800 V) to compensate for the decreased spectral bandwidth and total signal. The scan rate and data interval were decreased in order to enhance the resolution gains expected from the lower temperature analysis.

Several deltas were considered for the scans at synchronous settings. Previous work with oils recommended synchronous scanning be performed between Δ 20nm and 30 nm (Lloyd 1971) (VoDinh 1978). Initial runs of oils at Δ23nm, Δ70 nm, Δ90 nm, Δ105 nm at room temperature showed inconsistent results at the four deltas, with the greatest intensity observed at Δ23 nm and Δ70 nm. However, when the extracts from known motor vehicle locations were scanned at liquid nitrogen temperatures there was an overall drop in fluorescence intensity. A review of the room temperature EEMs showed that each known sample exhibited the most intense peaks at an emission wavelength

range between 280 nm to 290 nm (Ex. 220 nm) and a second group of peaks in an emission wavelength range of 330 nm to 340nm (Ex225 nm). Concerned that any Δ setting that did not intersect these peaks would show little-to-no fluorescence emission, I chose to proceed with the settings Δ70 nm and Δ105 nm. Ultimately, this may have been a redundant since these spectral characteristics were already being captured by individual excitation scans.

6. Fluorescence procedure

Low Temperature data collection occurred as a series of scans at three predetermined excitation wavelengths and two Δ λ in synchronous scanning mode. The wavelengths were chosen after review of the EEM matrices determined the areas of most intense fluorescence. Single scans and the average of 16 scans were captured for each excitation wavelength. Figure 25 below shows the increase in signal to noise that results from scan averaging. All analysis was done using the ensemble averaged scan produced from 16 successive excitation scans averaged together. Although spectral details varied among samples, Figure 26 below shows the typical result for the low temperature data collection. Low temperature fluorescence data was collected on all triplicate samples for each motor vehicle undercarriage location.

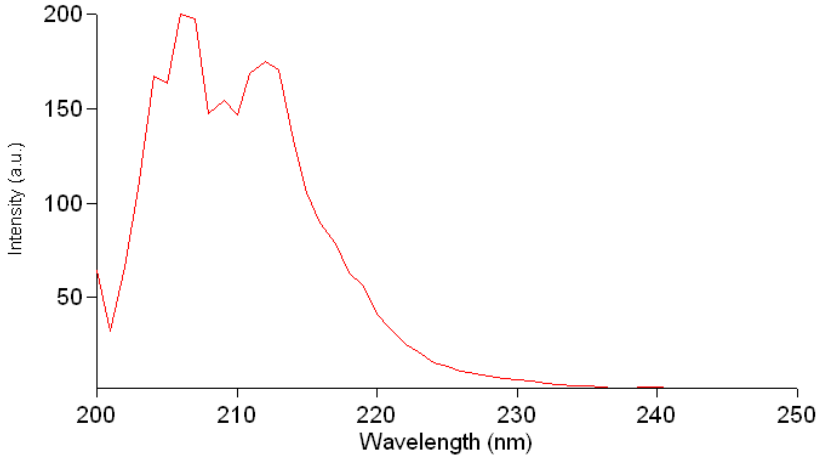
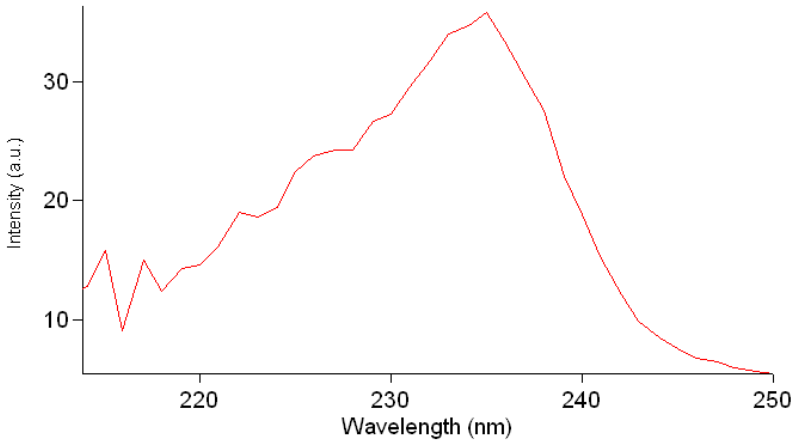
Synch Δ 70



Synch Δ 105



The emission wavelength range for the synchronous scans is 50 nm (200nm – 250 nm).

At this scale and data interval (1nm) it creates a jagged spectral appearance.

Figure 27. 51CT in Dewar at Room Temperature Ex. at 220 nm.

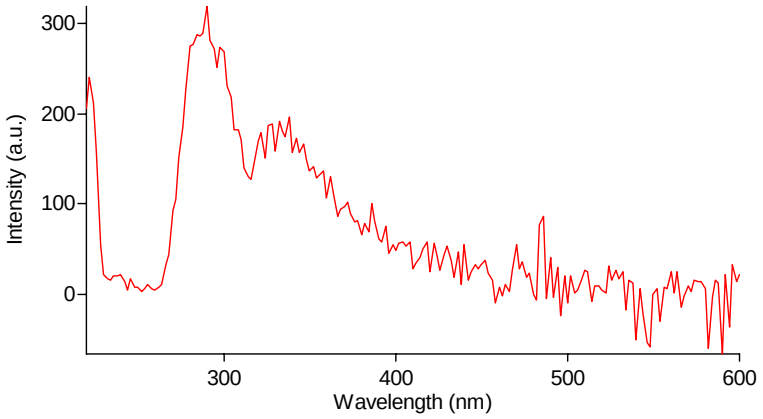


Figure 28. 51 CT in Dewar at 77 K Ex. at 220 nm.

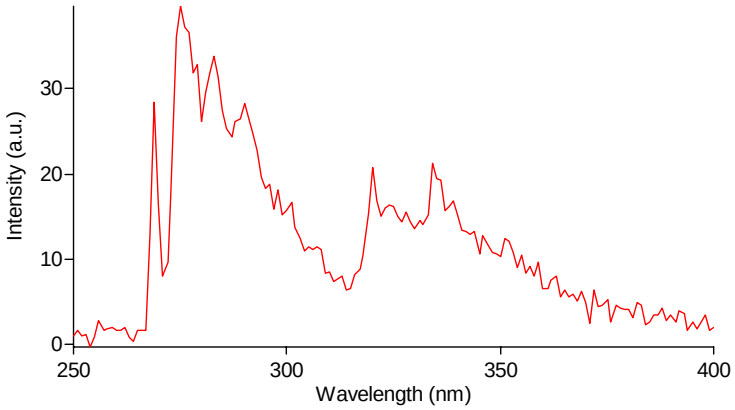


Spectral libraries were constructed using Grams Spectral ID software. All spectra collected at low temperature were converted individually into Grams files with the file extension ".spc". Three libraries were constructed using the emission scans of the toluene

extracts collected at excitation wavelengths 220 nm and 235 nm and with synchronous scan taken at Δ 70 nm. This extract type and these parameters yielded the most consistently intense spectra in the data set. All samples of unknown origin at these excitation and synchronous settings were searched against the libraries.

The Grams Spectral ID software allows for several types of library searches. All searches conducted for this study were correlation searches. The correlation setting uses an algorithm that centers the unknown and the library data about their means before a vector dot product is calculated (Grams/AI Help Resource). This means that the library and unknown spectra do not have to be normalized prior to searching. Upon searching, the unknown and the library entries are ranked by their hit quality index (H. Q. I.) this value represents the numeric rank of each comparison. The H.Q.I. values lie from zero for the best possible match to 1.000 to the worst. The closer the H.Q.I. is to zero, the better the hit.

Results

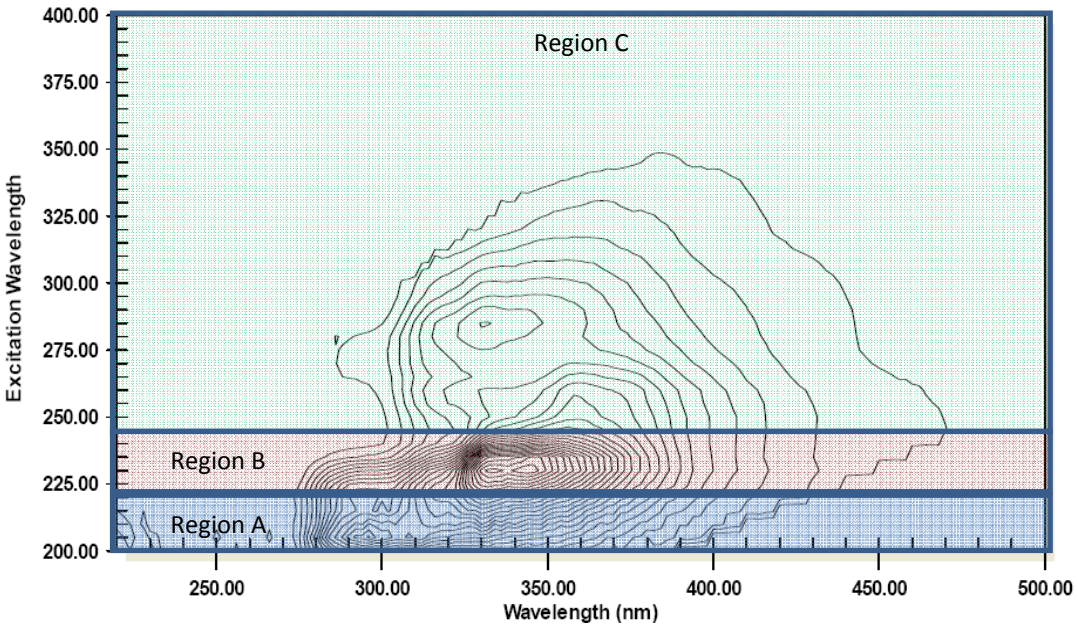
1. General Material Characteristics

There were observable differences between the residue colors, textures and ease of transfer from vehicle to vehicle. In general, older vehicles yielded greater quantities of transferable undercarriage residues which were more greasy than the residues from younger vehicles. Newer vehicles, especially the BMW 330xi, yielded less material per swab and this material was grittier and less oily than that found older cars. This implies that the tendency to transfer oils and other lubricants may be a function of age, use and vehicle design.

2. General Fluorescence Characteristics

In all fractions the most intense fluorescence was observed at excitations within the wavelength range of 200nm – 250nm. In the excitation wavelength range of 200nm-225nm it was common to find 1 or 2 peaks at emission wavelengths of 285-295 nm. Peaks found in this region of the EEM were labeled “Group A” peaks. In the excitation wavelength range of 225nm-250nm, and 2 additional peaks at emission wavelengths of 334nm and 345nm were observed. Peaks in this region of the EEM were labeled “Group B” peaks. The most intense fluorescence was usually observed in either the Group A or Group B region. All peaks found at excitations above 250nm are described as Region C peaks. While these were usually less intense than the peaks in Group A and B, it was in the Group C region where most of the variation from among samples was found. See Figure 29 below for a graphical representation of this peak grouping.

Figure 29. Region A, B, and C Excitation – Emission Regions. (Item 22A, pentane extract)



EEM spectra from the pentane and toluene extracts were grouped according to the number of peaks in each group and the excitation/emission λs all peaks present in Group C. After sorting with pentane extracts only, there were 22 unique groups, the largest with 11 vehicle locations and the smallest with 1. Results of this pentane extract peak classification are shown in Table 10.

The classifications performed using the pentane and toluene extracts were combined to achieve maximum discrimination. Each sample was labeled using a two value code; the first number is the pentane group and the second is the toluene group. These two numbers are shown for each sample below in Table 12. The undistinguished pairs are shown in gray.

Five pairs, shaded gray in Table 12, were indistinguishable using this method. Two of these pairs contain a known sample with sample of unknown origin. When the origin key was consulted it is found that one pair (M46 and 22) are incorrectly grouped together. Unknown M46 is not from vehicle 2 (Ford Bronco XLT) A second pair M19 and 54 were correctly grouped. They share a common origin. Unknown M19 is from vehicle 5 (Honda Accord). None of the other samples of unknown origin were correctly

identified using this classification method. Nine of the ten samples of unknown origin were not grouped with the known sample that came from the same vehicle location.

Since much of the variation between samples occurs in the Group C region of the EEM spectra, a second grouping scheme was used that relies solely on that peak number and position information was performed. This scheme did not result in improved associations.

Table 13 shows the results from the pyridine extract sample group. These data were not used in the classification scheme since so many of the EEMs exhibited very weak intensities. This made the identification of peaks in the Group A region (200 nm – 225 nm) impossible to determine from 19 of the knowns and 5 of the unknowns.

Table 13. Classification with Pyridine Extract EEM Spectra.

Pyridine Extract Groups	Sample	No. of Peaks in Group A	No. of Peaks in Group B	No. of Peaks in Group C	Group C Peak 1 (Ex., Em.) nm	Group C Peak 2 (Ex., Em.) nm	Group C Peak 3 (Ex., Em.) nm

The spectral classification scheme based on peak number and position proved to be highly distinguishing but not reproducible in this case. Combination of data from pentane and toluene extracts uniquely identified all but 5 pairs of samples. One of these pairs shared a common origin. However, this classification scheme was not successful at correctly associating the knowns with the samples of unknown origin. This could be due to the fact that known and unknown sample concentrations were adjusted using residue weight rather than HPLC data. Differences in concentration of fluorescing components are known to cause wavelength shifting. Samples at low concentrations could have experienced loss of smaller secondary peaks. If the unknown and the known exhibit different concentrations of fluorescing compounds they would be incorrectly grouped using a system that relies on peak number as well as peak position to classify spectra. This could also be due to the sample origins having a high degree of heterogeneity at the sample source itself. Every care was taken to ensure that the multiple swabs from the same vehicle location were applied evenly to the same areas. If the areas touched by the swabs varied in their composition of fluorescing compounds in that area then two swabs from the same vehicle location may contain very different compounds. This could occur if the original motor vehicle undercarriage residues exist as a layer or heterogeneous mixture were the sample composition could vary by grease-layer depth. A variation in the spectral classification scheme which relied only on Group C peaks (i.e. those at excitation λs above 250) did not yield more accurate results.

3. Low Temperature Fluorescence

The discriminating power of the fluorescence spectra from the low temperature data collection were determined using spectral libraries constructed using Grams Spectra ID software. Three libraries were constructed from the data generated from the toluene extracts; one at excitation wavelength 220 nm , a second at excitation wavelength 235 nm and a third at synchronous scanning Δ 70 nm.[11]

All 10 unknowns at each excitation (or synchronous) setting were searched against the libraries. Using the library of spectra collected at excitation 220 nm, 2 of the 10 unknowns were identified to the correct motor vehicle (M19 associated to 51A and 54A, M10 associated to 84C) in the top three library search results. And 1 of those associations was to the correct motor vehicle location (M19 and known 54A). Using the library of spectra collected at excitation 235 nm, 3 of the 10 unknowns were associated to the correct motor vehicle (M29 associated to 41A, M06 associated to 42A, M24 associated to 42A) in the top three results and 1 of those associations was to the correct motor vehicle specific location (M29 and known 41A). Using the library of spectra collected at synchronous Δ70 nm, 3 of the 10 unknowns were associated with the correct motor vehicle (M46 associated to 81A, M19 associated to 55A, and M24 associated to 41A) in the top three library search results. One of those associations was to correct motor vehicle location (M29 and known 41A). No other unknown was associated with

[11] The spectra generated at low temperature from the pyridine extracts were not used due their weak fluorescence intensity and their similarity to the peaks seen on the spectra from the toluene extracts.

their correct source motor vehicle. These results, along with the H.Q.I. values are summarized in the table below. The closer the H.Q.I value. is to zero, the better the library match.

Figure 30. Summary of hits obtained using spectral libraries. (Yellow = library search result to correct vehicle, pink = library search result to correct vehicle and specific location).

Interestingly, the one unknown that was correctly grouped with its exact motor vehicle source location with the comparison of EEM fluorescence spectra, M19, was also associated to the correct location (car 5 location 4) using the excitation = 220 nm spectral library. This indicates that the two methods are comparably ineffective at making correct associations between known and unknown. It should be noted that the top three library search results for each unknown as shown in the table above, rarely show matches to multiple samples from the same location. One would expect the triplicate swabs (i.e. the three swabs from the same vehicle and location) would be grouped together in the library search result list regardless of their overall position on that list. Since, this did not occur, it indicates that there is a fair amount of heterogeneity among the triplicate swabs taken from the same location. This could be due to actual compositional differences if the motor vehicle lubricants components vary with lubricants layer depth and are not a homogeneous mixture. Future studies should investigate alternative methods of residue collection designed to reduce this variability and collect more representative and homogeneous samples.

4. Characterization Using the HPLC Results

As previously stated, the chromatograms produced from extract solutions from triplicate swabs (i.e. three swabs from the same vehicle location) demonstrated excellent reproducibility and inter-vehicle-location variability in peak size, retention time and size and shape of the unresolved envelope. However, the technique was not used to determine concentration prior to fluorescence due to solvent incompatibility issues. The

chromatograms produced from the swabs of unknown origin were compared to these known sets on four criteria and the outcomes reported in the results section. Comparisons of the knowns to the samples of unknown origin were based on both numeric (peak retentions time) and spatial (unresolved envelope shape) characteristics. The table below shows each unknown and the predicted vehicle origins from the HPLC data and the actual origins as documented in the unknown key created by Ms. Grimly. The results show 7 of 10 correct associations made to vehicles with 6 of 10 to exact to the specific location on that vehicle. This data exhibits far better associative results than those achieved from the examination of peak number and position of EEM plots. This is especially remarkable considering that these data were collected in a solvent system designed for complete elution and maintenance of a stable baseline rather than optimum peak resolution and qualitative analysis.

Number of correct vehicle location associations = 6 of 10.

Discussion

In this study, three analytical data sets were collected: room temperature EEM fluorescence, low temperature excitation and synchronous averaged scans at selected wavelengths, and chromatograms from the pentane extracts. Of those three, the chromatographic data exhibited the most agreement among triplicate swabs from the same motor vehicle location and more importantly, the best ability to associate motor vehicles of an unknown origin to the known collected from the same motor vehicle location.

Conclusion 1

Three-dimensional fluorescence spectroscopy, as performed in this experiment, and collected at room temperature, of motor vehicle undercarriage residues is highly distinguishing but unreliable for the successful association of residues of unknown origin to their source motor vehicles by the methods employed in this study.

Excitation-emission matrices are excellent representations of the overall fluorescence emission characteristics of a material. The ability to display data at multiple excitation wavelengths as a contour plot is a simple way to represent a large amount of spectral data. This type of data presentation is best suited to observe gross characteristics of fluorescence spectra (e.g. the number and position of multiple peaks at multiple wavelengths). It is not suitable for the representation of fine spectral detail. In this study, fluorescence EEMs were not a good tool to distinguish among motor vehicle residues with similar compositions from different sources.

Regarding the usefulness of this technique to distinguish among motor vehicle residues, an analogy can be made between the motor vehicle grease residues and the highly complex mixtures encountered during the analysis of ignitable liquid residues (ILRs) from fire debris. Ignitable liquid residues are multicomponent mixtures produced mostly from the refining of petroleum, that through use and exposure are subject to degradation and weathering. Gas chromatography – mass spectrometry (GC/MS) is the preferred analytical instrumentation for ILRs because it performs the separation of complex mixtures and supplies the mass spectral data necessary to identify compounds. If GC/MS is not available, the GC with a flame ionization detector will be able to identify many of the known ILRs through comparison of chromatographic patterns. Complex mixtures are not suitable for analysis by mass spectrometry alone. As chromatographic separation is more useful than the spectral data for the identification of ILRs of unknown origin, the same appears to be true of motor vehicle undercarriage residues.[12]

Effectiveness of the Extraction Method

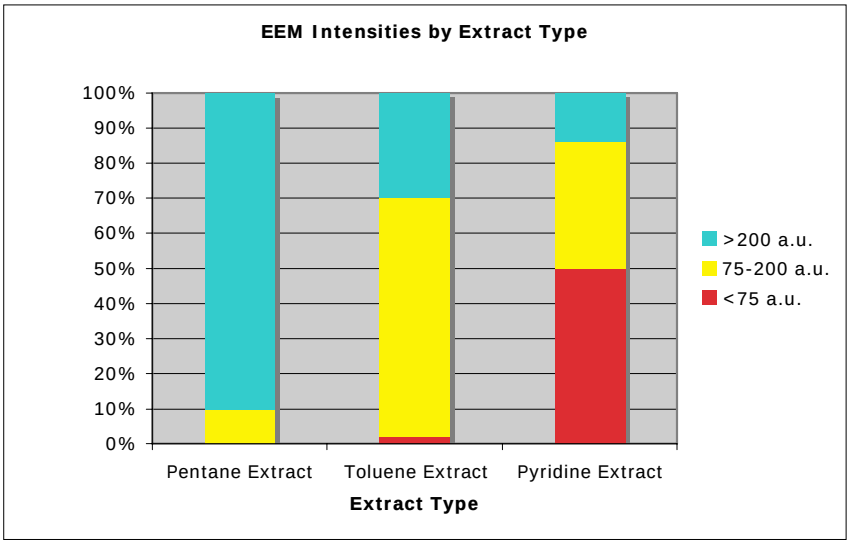
The three-solvent extraction system was adopted in order to separate the motor vehicle residues into three distinct compound classes. In all extracts, the peaks in the Group A and B regions were the most intense and the variations peak λ maxima were not consistent among extracts from different solvents. This indicates that the three solvent extraction system did not result in three fractions with different groups of fluorophores.

[12] This analogy is not meant to equate mass and optical spectral data, just their usefulness in analyzing complex mixtures.

The Group C region of the EEM (excitations above 250nm) exhibited some spectral differences from in each extraction type. Ultimately, the fluorescence spectra data set from the successive three-solvent extraction system did not successfully associate the ten samples of unknown origin with the motor vehicles of origin.

Since the overall fluorescence intensity decreased with each successive extraction type (pentane → toluene → pyridine) along with the number of peaks observed, I advise that future research proceed with a single extraction procedure designed to maximize extractions of fluorescing compound types. Figure 31 shows how the fluorescence intensity of the most intense peak observed in the excitation emission matrix changed with each extraction.

Figure 31. Percentage of EEMs collected and the distribution of Fluorescent intensities. N=50



This decrease in intensity seen from the first extraction (pentane) to the third (pyridine) could be due to two factors. First, the three solvent extraction system successfully separated the motor vehicle residues in the oil, asphaltene and pre-asphaltene fractions and fluorescence component of the total extract residue decreased with each class of compounds. Or, second, the extraction system was not successful at the separation by compound class and the total fluorescing component of the motor vehicle undercarriage residue was unevenly distributed among the three fractions. Since no qualitative analysis of individual compounds in each fraction was performed it is not possible to opine on the actual components of the extractions. The fact that all three extract types exhibited their major peaks at the same excitation ranges (200 nm – 250 nm) that all three contained similar compound types, however, the less intense peaks present in the group C region (>250 nm) indicate compositional differences between the pyridine extracts and the other two solvent extracts.

Conclusion 2

In this study, adjusting concentration of extract residue solutions based on residue mass (e.g. w/w ppm) did not adjust all the fluorescing components of each triplicate swab to the same concentration.

Using total residue weights to bring motor vehicle undercarriage residues from the sample source location to a common concentration did not result in common fluorescent intensities among samples from the same source. It was thought that if the ratio of fluorescence compounds was the same in each swab from the same motor vehicle

location, then adjusting concentration based on to the total extract mass would also bring the fluorescing compounds to a common concentration. Since the fluorescent intensities of the major peaks in spectra from each triplicate sample were not the same, this was not the case.

Without adjusting the concentration of the fluorescencing compounds alone it is not possible to know if weak fluorescence emission observed in one sample, but not in another, is due to the compositional or concentration differences. This could lead to false exclusions in very dilute samples.

Conclusion 3

In the conditions used in this study, low temperature fluorescence emission scans, collected at 77K, of motor vehicle undercarriage residues exhibit increased resolution but are not reliable for the successful association of residues of unknown origin to their source motor vehicles.

The spectra collected at 77K exhibited increased resolution. This technique has some specific challenges. The sample compartment must be kept at extremely low humidity and dry nitrogen gas must flow at all times onto the tip of the Dewar in order to keep it frost free. The long sample tubes require an extensive cleaning procedure to ensure no sample carryover. After each cleaning, the tubes were scanned with the sample solvent to ensure that there was no carry-over from one sample to the next. The tubes

themselves are subject to breakage if the frozen solution is warmed too quickly. Clear freezes are only accomplished if the tube itself is lowered very slowly into the liquid nitrogen. Despite these disadvantages, the apparatus itself is very useful for generating spectra of increased resolution. However the observed increase in resolution did not result in an increased ability to distinguish among motor vehicle undercarriage residues, nor did it allow for a more successful association of the unknown residues with their respective source vehicles.

Conclusion 4

In this study, chromatography of motor vehicle undercarriage residues was better than room temperature or low temperature fluorescence spectroscopy at both discriminating among vehicle locations and making correct associations between samples of known origin and samples of unknown origin.

The successful associations made using the chromatographic data (7/10 unknown origin vehicles and 6/10 unknown vehicle locations) have important implications for future research. These data were produced primarily to determine concentration. They were not collected under conditions meant to optimize resolution and specific peak identification. The primary goal was to accomplish complete elution of all compounds injected to avoid carryover and then use total peak areas to represent overall concentration. Solvent incompatibility between the low temperature apparatus and the

HPLC system resulted in the a design shift to determine concentration by residue weights instead. The chromatographic data set exhibited poor peak resolution but excellent reproducibility among triplicate knowns and variation in chromatographic patterns between knowns. As a result the chromatographic data was more useful as a means to associate samples of unknown origin to their source vehicles rather than as a means to adjust concentration.

Conclusion 5

The low temperature apparatus, as designed, can be used to successfully generate fluorescence spectra that exhibit greater resolution than room temperature measurement.

The low temperature apparatus, after extensive modification and testing, can be used to produce fluorescence spectra with better resolution than room temperature data collection. Once frozen, the rigid matrix successfully inhibits band broadening due to non-radiative relaxation of excited fluorophores. This increase in resolution was accompanied by a decrease in fluorescence intensity.

The low temperature apparatus was successfully used to generate spectra with better resolution. This technique would be very useful to research projects that aim to better understand the specific electronic transitions that occur during fluorescence

emission. Future work with low temperature fluorescence for characterization of motor vehicle residues should proceed once a Dewar is obtained that can maintain a single freeze, without refilling the Dewar, for at least 30 minutes. This will provide enough time to obtain an excitation emission matrix data set for each sample. Low temperature work in this study was limited to the collection of scans at several excitation wavelengths. This did not provide the spectral detail necessary to successfully distinguish between motor vehicles nor did it provide enough information to make successful associations among all the samples of unknown origin and known samples using spectral library searching software. Additionally, future work should investigate alternative fluorescence instrumentation available to collect fluorescence spectra at low temperature.

Recommendation 1

I recommend that future research not use fluorescence excitation emission matrices, collected under the parameters used in this study, to distinguish among motor vehicles undercarriage residues until a suitable method is developed to establish the concentration of fluorescent materials in the sample. Basing sample concentration on the mass of all compounds extracted, as opposed to, relative amount of fluorescence compounds does not result in spectra of similar fluorescent intensity for samples from the same source motor vehicle.

Recommendation 2

Based on the results of these experiments, I do not recommend that low temperature fluorescence be used to distinguish among different sources of automotive undercarriage residue until a more reliable method of determining sample concentration is developed, most likely though a chromatographic process, and until an instrument design is identified that better suits the needs of the quartz-tipped Dewar.

This work confirms the recommendation made by Purcell about the concentration adjustments necessary to sample prior to collection of fluorescence spectral data. Residue weights are not ideal as they do not represent the overall concentration of the fluorescing compounds in the sample. Chromatographic methods that are more compatible with the solvent needs of low temperature analysis are necessary.

Recommendation 3

Future work should use HPLC with fluorescence detection to characterize motor vehicle undercarriage residues.

If successful associations can be made using a simple isocratic elution method with single wavelength UV absorbance detection methods, then it stands to reason that improvements in individualization will be obtained at conditions of higher chromatographic resolution and sensitivity. I recommend that future work be done using

HPLC with fluorescence detection. A fluorescence detection system would provide a better sensitivity than UV absorbance detection.

Impact on Criminal Justice and Forensic Science Policy and Practice

The contribution of this research to the field of forensic science is the advancement of knowledge about the analytical techniques applied to a long-observed transferable material, motor vehicle undercarriage residue, to attempt to create associations between automobiles and persons or objects. When the best analytical technique is identified, these associations can be used to help the trier of fact determine the likelihood that a specific automobile came into contact with a person or object. This project illustrates the inability of room temperature three dimensional fluorescence spectroscopy and low temperature two dimensional fluorescence spectroscopy to discriminate among transferred petroleum materials. This type of evidence can be found in "hit and run" type vehicular crimes.

Analysis of transfer evidence is one of the oldest and most challenging types of forensic analysis due to the limitless number of material types that may transfer between persons and/or objects during the commission of a criminal act. (Houck, 2001) The vast majority of the resources provided to forensic science laboratories and forensic science researchers through federal funding are put towards the forensic disciplines that are able to identify suspects through direct associations (i.e. DNA and fingerprints) (NAS, 2009).

While there is no doubt that both are very powerful investigative tools, the narrowing field-of-view by both funders and criminal justice researchers could have the unforeseen consequence of the underdevelopment of new and novel transfer evidence analysis techniques.

Transfer evidence is highly variable in composition and mode of transfer. The analyst must master a myriad of identification and quantification methods in order to proficiently analyze physical evidence. This research sought to add tools to the forensic chemist's arsenal in order to expand the impact of this forensic discipline. The conclusions of this project and the recommendations made for future research expand the body of knowledge about this form of transfer evidence and about the lessons one can apply from traditional oil and grease analysis.

This project is one of many that have investigated the discriminating power of an instrumental technique on a specific class of materials. Motor vehicle undercarriage residues have been observed as transferred materials in casework but are not routinely reported as a subset of forensic chemistry (Durose, 2008). The conclusions of this research project may be used to guide future research that continues to seek the optimal analytical tools needed to distinguish among motor vehicle undercarriage residues. Once future research identifies that method, more forensic laboratories may include oil and grease analysis in their forensic chemistry sections, thereby increasing the evidentiary

value of this physical evidence type as well as the impact of transfer evidence analysis on criminal investigations and prosecutions.

Summary

Overall, the fluorescence and chromatographic techniques used to differentiate transferred vehicle undercarriage residue from different vehicle locations and to associate samples of unknown origin with the correct source vehicle have been produced results of varying reliability. Chromatographic data proved to be more reliable than spectral data for this purpose. In this study and with the instrumentation used, the EEM contour plots collected at room temperature with overlapping excitation scans produced sufficient variation to differentiate most motor vehicle samples but did not successful associate most the unknown samples. The single scans taken at low temperature exhibited increased peak resolution than room temperature scans but the spectral detail in the five wavelengths collected (three excitation and two synchronous) were not sufficient to differentiate most samples through visual comparison alone. In this study, searching with spectral libraries produced increased differentiation but were also not more successful than visual examination of room temperature EEMs at the correct association of unknowns with known vehicle locations. It would be advantageous to combine the EEM data collection with the increased resolution of the low temperature environments. Any future work using fluorescence EEM to distinguish among motor vehicle undercarriage residues should utilize alternative fluorescence spectrometers that allow the user to have greater control over instrument parameters. Most surprising was the ability of

chromatographic data, collected under isocratic conditions, to correctly associate most of the unknown motor vehicle residues while exhibiting excellent reproducibility among the triplicate samples. Future work in this area should focus on the use of HPLC coupled with fluorescence detection to combine the best of each of these methods to differentiate among transferred vehicle petroleum products.

Appendix B. Cary Eclipse Specifications

Cary Eclipse Specifications:

Monochromators

Excitation: Czerny-Turner, f3.6, 0.125 m focal length,

Emission: Czerny-Turner, f3.6, 0.125 m focal length,

Gratings

Excitation: 30 x 35 mm, 1200 l/mm, blaze at 370 nm,

Emission: 30 x 35 mm, 1200 l/mm, blaze at 440 nm

- All reflective optical system with quartz over-coated optics.
- Schwarzschild source optics for increased energy throughput and precise imaging and focusing.
- 80 data points per second maximum measurement rate in fluorescence mode.
- non- measurement phase stepping wavelength drive.
- room light immunity in fluorescence mode,
- Source Xenon pulse lamp with exceptionally long lifetime, pulsed at 80 Hz. Pulse width at half peak height ~ 2 µs, peak power equivalent to 75 kW.

Wavelength range (nm)

Mechanical

Excitation: 190 to 1100 nm. Zero order selectable.

Emission: 190 to 1100 nm. Zero order selectable.

Operational

Excitation: 200 to 900 nm with standard PM tube. Zero order selectable.

Emission: 200 to 900 nm with standard PM tube. Zero order selectable.

Wavelength accuracy (nm) ± 1.5 nm

Wavelength reproducibility (nm) ± 0.2 nm

Detectors

High performance R928 photomultiplier detector and separate R928 PMT

for reference signal.

Sensitivity (Raman Band of Water)

>500:1 RMS, 500 nm excitation, excitation and emission slits 10 nm, 1 sec Signal Averaging time. >750:1 RMS, 350 nm excitation, excitation and emission slits 10 nm, 1 sec Signal Averaging time.
